

TIME SERIES

A.W. van der Vaart

Universiteit Leiden

version 242013

PREFACE

These are lecture notes for the courses “Tijdreeksen”, “Time Series” and “Financial TimeSeries”. The material is more than can be treated in a one-semester course. See next section for the exam requirements.

Parts marked by an asterisk “*” do not belong to the exam requirements.

Exercises marked by a single asterisk “*” are either hard or to be considered of secondary importance. Exercises marked by a double asterisk “**” are questions to which I do not know the solution.

Amsterdam, 1995–2010 (revisions, extensions),

A.W. van der Vaart

LITERATURE

The following list is a small selection of books on time series analysis. Azencott/Dacunha-Castelle and Brockwell/Davis are close to the core material treated in these notes. The first book by Brockwell/Davis is a standard book for graduate courses for statisticians. Their second book is prettier, because it lacks the overload of formulas and computations of the first, but is of a lower level.

Chatfield is less mathematical, but perhaps of interest from a data-analysis point of view. Hannan and Deistler is tough reading, and on systems, which overlaps with time series analysis, but is not focused on statistics. Hamilton is a standard work used by econometricians; be aware, it has the existence results for ARMA processes wrong. Brillinger's book is old, but contains some material that is not covered in the later works. Rosenblatt's book is new, and also original in its choice of subjects. Harvey is a proponent of using system theory and the Kalman filter for a statistical time series analysis. His book is not very mathematical, and a good background to state space modelling.

Most books lack a treatment of developments of the last 10–15 years, such as GARCH models, stochastic volatility models, or cointegration. Mills and Gouriéroux fill this gap to some extent. The first contains a lot of material, including examples fitting models to economic time series, but little mathematics. The second appears to be written for a more mathematical audience, but is not completely satisfying. For instance, its discussion of existence and stationarity of GARCH processes is incomplete, and the presentation is mathematically imprecise at many places. An alternative to these books are several review papers on volatility models, such as Bollerslev et al., Ghysels et al., and Shepard. Besides introductory discussion, also including empirical evidence, these have extensive lists of references for further reading.

The book by Taniguchi and Kakizawa is unique in its emphasis on asymptotic theory, including some results on local asymptotic normality. It is valuable as a resource.

Introduction

Oddly enough, a statistical time series is a mathematical *sequence*, not a series. In this book we understand a *time series* to be a doubly infinite sequence

$$\dots, X_{-2}, X_{-1}, X_0, X_1, X_2, \dots$$

of random variables or random vectors. We refer to the index t of X_t as *time* and think of X_t as the state or output of a stochastic system at time t . The interpretation of the index as “time” is unimportant for the mathematical theory, which is concerned with the joint distribution of the variables only, but the implied ordering of the variables is usually essential. Unless stated otherwise, the variable X_t is assumed to be real valued, but we shall also consider sequences of random vectors X_t , or variables with values in the complex numbers. We often write “the time series X_t ” rather than use the correct $(X_t: t \in \mathbb{Z})$, and instead of “time series” we also speak of “process”, “stochastic process”, or “signal”.

We are interested in the joint distribution of the variables X_t . The easiest way to ensure that these variables, and other variables that we may introduce, possess joint laws, is to assume that they are defined as measurable maps on a single underlying probability space. This is what we meant, but did not say in the preceding definition. Also in general we make the underlying probability space explicit only if otherwise confusion might arise, and then denote it by (Ω, \mathcal{U}, P) , with ω denoting a typical element of Ω and $X_t(\omega)$ the *realization* of the variable X_t .

1.1 Stationarity

Time series theory is a mixture of probabilistic and statistical concepts. The probabilistic part is to study and characterize probability distributions of sets of variables X_t that will typically be dependent. The statistical problem is to determine the probability distribu-

tion of the time series given observations X_1, \dots, X_n at times $1, 2, \dots, n$. The resulting stochastic model can be used in two ways:

- understanding the stochastic system;
- predicting the “future”, i.e. X_{n+1}, X_{n+2}, \dots .

In order to have any chance of success at these tasks it is necessary to assume some a-priori structure of the time series. Indeed, if the X_t could be completely arbitrary random variables, then (X_1, \dots, X_n) would constitute a single observation from a completely unknown distribution on \mathbb{R}^n . Conclusions about this distribution would be impossible, let alone about the distribution of the future values X_{n+1}, X_{n+2}, \dots .

A basic type of structure is stationarity. This comes in two forms.

1.1 Definition. *The time series X_t is strictly stationary if the distribution (on \mathbb{R}^{h+1}) of the vector $(X_t, X_{t+1}, \dots, X_{t+h})$ is independent of t , for every $h \in \mathbb{N}$.*

1.2 Definition. *The time series X_t is stationary (or more precisely second order stationary) if EX_t and $EX_{t+h}X_t$ exist and are finite and do not depend on t , for every $h \in \mathbb{N}$.*

It is clear that a strictly stationary time series with finite second moments is also stationary. For a stationary time series the *auto-covariance* and *auto-correlation* at lag $h \in \mathbb{Z}$ are defined by

$$\begin{aligned}\gamma_X(h) &= \text{cov}(X_{t+h}, X_t), \\ \rho_X(h) &= \rho(X_{t+h}, X_t) = \frac{\gamma_X(h)}{\gamma_X(0)}.\end{aligned}$$

The auto-covariance and auto-correlation are functions $\gamma_X: \mathbb{Z} \rightarrow \mathbb{R}$ and $\rho_X: \mathbb{Z} \rightarrow [-1, 1]$. Both functions are symmetric about 0. Together with the mean $\mu = EX_t$, they determine the first and second moments of the stationary time series. Much of time series (too much?) concerns this “second order structure”.

The autocovariance and autocorrelations functions are measures of (linear) dependence between the variables at different time instants, except at lag 0, where $\gamma_X(0) = \text{var } X_t$ gives the variance of (any) X_t , and $\rho_X(0) = 1$.

1.3 Example (White noise). A doubly infinite sequence of independent, identically distributed random variables X_t is a strictly stationary time series. Its auto-covariance function is, with $\sigma^2 = \text{var } X_t$,

$$\gamma_X(h) = \begin{cases} \sigma^2, & \text{if } h = 0, \\ 0, & \text{if } h \neq 0. \end{cases}$$

Any stationary time series X_t with mean zero and covariance function of this type is called a *white noise* series. Thus any mean-zero i.i.d. sequence with finite variances is a white noise series. The converse is not true: there exist white noise series that are not strictly stationary.

The name “noise” should be intuitively clear. We shall see why it is called “white” when discussing spectral theory of time series in Chapter 6. \square

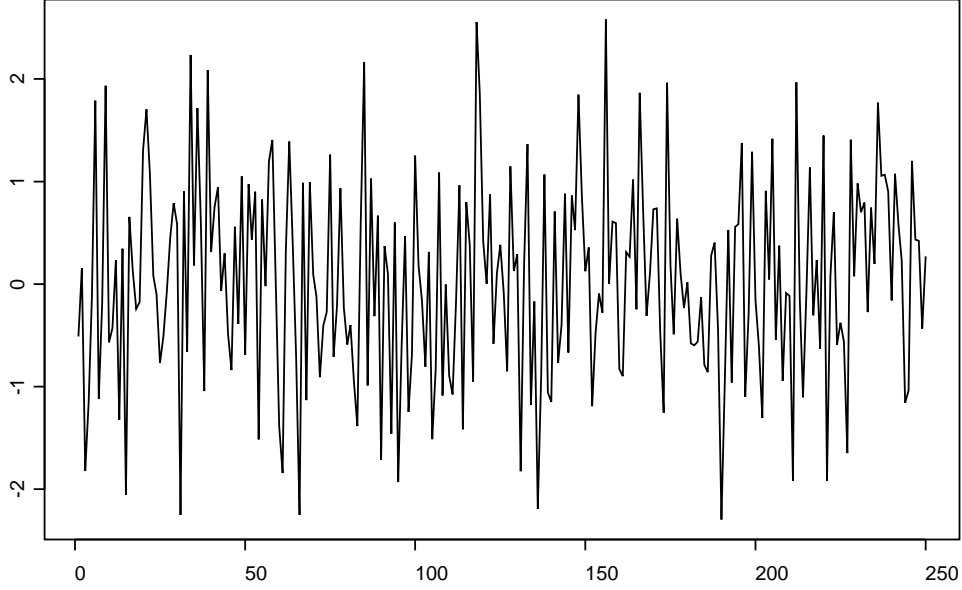

Figure 1.1. Realization of a Gaussian white noise series of length 250.

1.4 EXERCISE. Construct a white noise sequence that is not strictly stationary.

White noise series as in the preceding example are important building blocks to construct other series, but from the point of view of time series analysis they are not so interesting. More interesting are series of dependent random variables, so that, to a certain extent, the future can be predicted from the past.

1.5 Example (Deterministic trigonometric series). Let A and B be given, uncorrelated random variables with mean zero and variance σ^2 , and let λ be a given number. Then

$$X_t = A \cos(t\lambda) + B \sin(t\lambda)$$

defines a stationary time series. Indeed, $EX_t = 0$ and

$$\begin{aligned} \gamma_X(h) &= \text{cov}(X_{t+h}, X_t) \\ &= \cos((t+h)\lambda) \cos(t\lambda) \text{var } A + \sin((t+h)\lambda) \sin(t\lambda) \text{var } B \\ &= \sigma^2 \cos(h\lambda). \end{aligned}$$

Even though A and B are random variables, this type of time series is called *deterministic* in time series theory. is because once A and B have been determined (at time $-\infty$ say),

the process behaves as a deterministic trigonometric function. This type of time series is an important building block to model cyclic events in a system, but it is not the typical example of a statistical time series that we study in this course. Predicting the future is too easy in this case. \square

1.6 Example (Moving average). Given a white noise series Z_t with variance σ^2 and a number θ set

$$X_t = Z_t + \theta Z_{t-1}.$$

This is called a *moving average* of order 1. The series is stationary with $EX_t = 0$ and

$$\gamma_X(h) = \text{cov}(Z_{t+h} + \theta Z_{t+h-1}, Z_t + \theta Z_{t-1}) = \begin{cases} (1 + \theta^2)\sigma^2, & \text{if } h = 0, \\ \theta\sigma^2, & \text{if } h = \pm 1, \\ 0, & \text{otherwise.} \end{cases}$$

Thus X_s and X_t are uncorrelated whenever s and t are two or more time instants apart. We speak of *short range dependence* and say that the time series has *short memory*. Figure 1.2 shows a realization of a moving average series; at first glance it does not look that different from the realization of an i.i.d. sequence.

If the Z_t are an i.i.d. sequence, then the moving average is strictly stationary.

A natural generalization are higher order moving averages of the form $X_t = Z_t + \theta_1 Z_{t-1} + \dots + \theta_q Z_{t-q}$. \square

1.7 EXERCISE. Prove that the series X_t in Example 1.6 is strictly stationary if Z_t is a strictly stationary sequence.

1.8 Example (Autoregression). Given a white noise series Z_t with variance σ^2 and a number θ consider the equations

$$X_t = \theta X_{t-1} + Z_t, \quad t \in \mathbb{Z}.$$

To give this equation a clear meaning, we take the white noise series Z_t as defined on some probability space (Ω, \mathcal{U}, P) , and look for a solution X_t to the equation: a time series defined on the same probability space that solves the equation “pointwise in ω ” (at least for almost every ω).

The autoregressive equation does not define X_t , but in general has many solutions. Indeed, we can define the sequence Z_t and the variable X_0 in some arbitrary way on the given probability space and next define the remaining variables X_t for $t \in \mathbb{Z} \setminus \{0\}$ by the equation. However, suppose that we are only interested in *stationary* solutions. Then there is either no solution or a unique solution, depending on the value of θ , as we shall now prove.

Suppose first that $|\theta| < 1$. By iteration we find that

$$\begin{aligned} X_t &= \theta(\theta X_{t-2} + Z_{t-1}) + Z_t = \dots \\ &= \theta^k X_{t-k} + \theta^{k-1} Z_{t-k+1} + \dots + \theta Z_{t-1} + Z_t. \end{aligned}$$

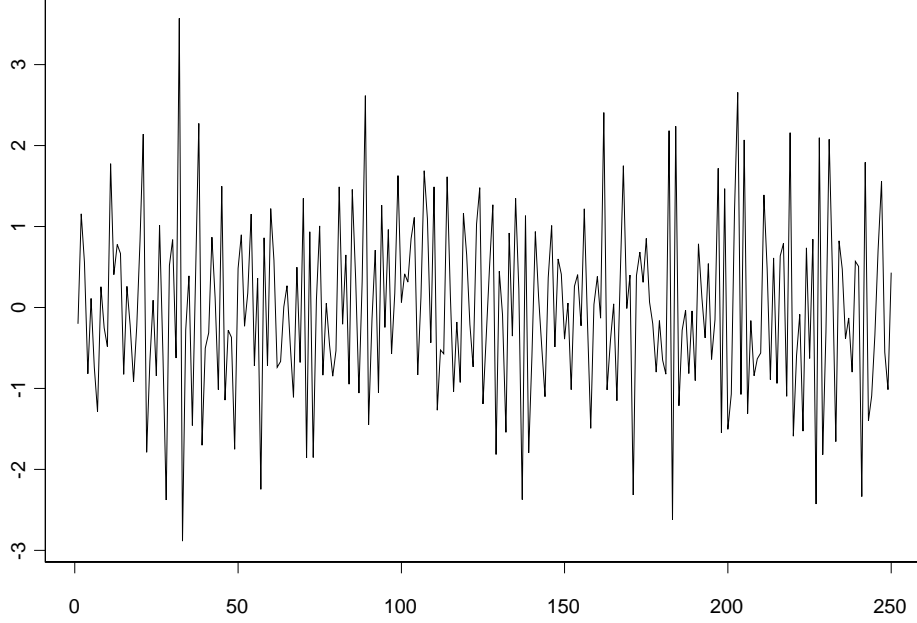

Figure 1.2. Realization of length 250 of the moving average series $X_t = Z_t - 0.5Z_{t-1}$ for Gaussian white noise Z_t .

For a stationary sequence X_t we have that $E(\theta^k X_{t-k})^2 = \theta^{2k} EX_0^2 \rightarrow 0$ as $k \rightarrow \infty$. This suggests that a solution of the equation is given by the infinite series

$$X_t = Z_t + \theta Z_{t-1} + \theta^2 Z_{t-2} + \cdots = \sum_{j=0}^{\infty} \theta^j Z_{t-j}.$$

We show below in Lemma 1.29 that the series on the right side converges almost surely, so that the preceding display indeed defines some random variable X_t . This is a “moving average of infinite order”. We can check directly, by substitution in the equation, that X_t satisfies the auto-regressive relation. (For every ω for which the series converges; hence in general only almost surely. We consider this to be good enough.)

If we are allowed to change expectations and infinite sums, then we see that

$$\begin{aligned} EX_t &= \sum_{j=0}^{\infty} \theta^j EZ_{t-j} = 0, \\ \gamma_X(h) &= \sum_{i=0}^{\infty} \sum_{j=0}^{\infty} \theta^i \theta^j EZ_{t+h-i} Z_{t-j} = \sum_{j=0}^{\infty} \theta^{h+j} \theta^j \sigma^2 1_{h+j \geq 0} = \frac{\theta^{|h|}}{1 - \theta^2} \sigma^2. \end{aligned}$$

We justify these computations in Lemma 1.29. It follows that X_t is indeed a stationary time series. In this example $\gamma_X(h) \neq 0$ for every h , so that every pair of variables X_s and X_t are dependent. However, because $\gamma_X(h) \rightarrow 0$ at exponential speed as $h \rightarrow \infty$, this series is still considered to be short-range dependent. Note that $\gamma_X(h)$ oscillates if $\theta < 0$ and decreases monotonely if $\theta > 0$. The realization in Figure 1.4 shows more dependence than in a moving average series.

For $\theta = 1$ the situation is very different: no stationary solution exists. To see this note that the equation obtained before by iteration now takes the form, for $k = t$,

$$X_t = X_0 + Z_1 + \cdots + Z_t.$$

Thus X_t is a *random walk*. It satisfies $\text{var}(X_t - X_0) = t\sigma^2 \rightarrow \infty$ as $t \rightarrow \infty$. However, by the triangle inequality we have that

$$\text{sd}(X_t - X_0) \leq \text{sd } X_t + \text{sd } X_0 = 2 \text{sd } X_0,$$

for a stationary sequence X_t . Hence no stationary solution exists. The situation for $\theta = 1$ is *explosive*: the randomness increases significantly as $t \rightarrow \infty$ due to the introduction of a new Z_t for every t . Figure 1.3 illustrates the nonstationarity of a random walk.

The cases $\theta = -1$ and $|\theta| > 1$ are left as exercises.

The auto-regressive time series of order one generalizes naturally to auto-regressive series of the form $X_t = \phi_1 X_{t-1} + \cdots + \phi_p X_{t-p} + Z_t$. The existence of stationary solutions X_t to this equation depends on the locations of the roots of the polynomial $z \mapsto 1 - \phi_1 z - \phi_2 z^2 - \cdots - \phi_p z^p$, as is discussed in Chapter 8. \square

1.9 EXERCISE. Consider the cases $\theta = -1$ and $|\theta| > 1$. Show that in the first case there is no stationary solution and in the second case there is a unique stationary solution. [For $|\theta| > 1$ mimic the argument for $|\theta| < 1$, but with time reversed: iterate $X_{t-1} = (1/\theta)X_t - Z_t/\theta$.]

1.10 Example (GARCH). A time series X_t is called a *GARCH(1, 1) process* if, for given nonnegative constants α , θ and ϕ , and a given i.i.d. sequence Z_t with mean zero and unit variance, it satisfies the system of equations

$$(1.1) \quad \begin{aligned} X_t &= \sigma_t Z_t, \\ \sigma_t^2 &= \alpha + \phi \sigma_{t-1}^2 + \theta X_{t-1}^2. \end{aligned}$$

The variable σ_t is interpreted as the scale or *volatility* of the time series X_t at time t . By the second equation this is modelled as dependent on the “past”. To make this structure explicit it is often included (or thought to be automatic) in the definition of a GARCH process that, for every t ,

- (i) σ_t is a measurable function of X_{t-1}, X_{t-2}, \dots ;
 - (ii) Z_t is independent of X_{t-1}, X_{t-2}, \dots .
- In view of the first GARCH equation, properties (i)-(ii) imply that

$$\begin{aligned} EX_t &= E\sigma_t EZ_t = 0, \\ EX_s X_t &= E(X_s \sigma_t) EZ_t = 0, \quad (s < t). \end{aligned}$$

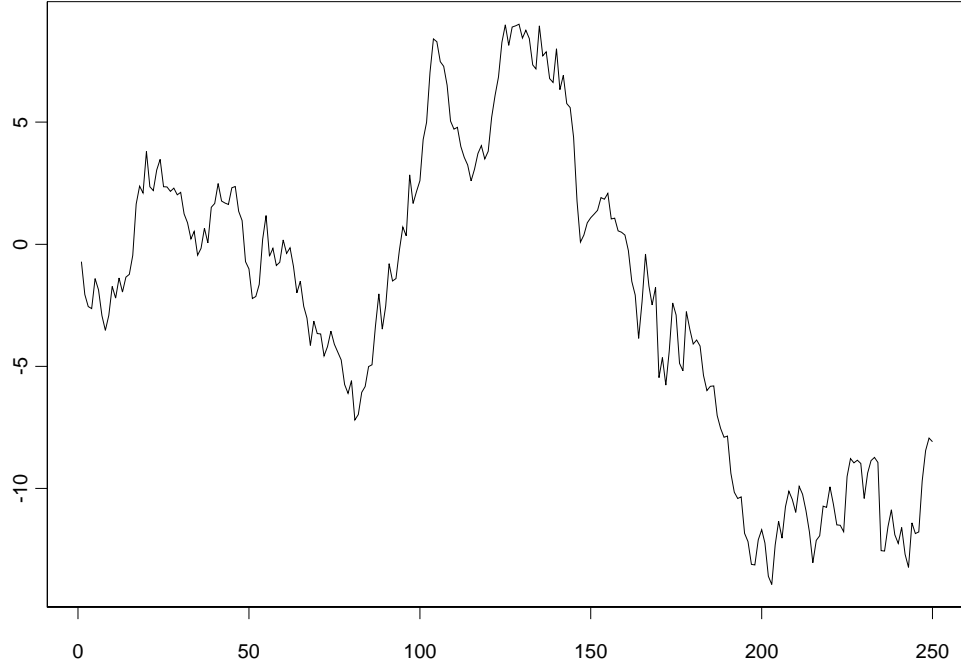

Figure 1.3. Realization of a random walk $X_t = Z_t + \dots + Z_0$ of length 250 for Z_t Gaussian white noise.

Therefore, a GARCH process with the extra properties (i)-(ii) is a white noise process. Furthermore,

$$\begin{aligned} E(X_t | X_{t-1}, X_{t-2}, \dots) &= \sigma_t E Z_t = 0, \\ E(X_t^2 | X_{t-1}, X_{t-2}, \dots) &= \sigma_t^2 E Z_t^2 = \sigma_t^2. \end{aligned}$$

The first equation shows that X_t is a “martingale difference series”: the past does not help to predict future values of the time series. The second equation exhibits σ_t^2 as the conditional variance of X_t given the past. Because σ_t^2 is a nontrivial time series by the second GARCH equation (if $\phi + \theta \neq 0$), the time series X_t is not an i.i.d. sequence.

Because the conditional mean of X_t given the past is zero, a GARCH process will fluctuate around the value 0. A large deviation $|X_{t-1}|$ from 0 at time $t-1$ will cause a large conditional variance $\sigma_t^2 = \alpha + \theta X_{t-1}^2 + \phi \sigma_{t-1}^2$ at time t , and then the deviation of $X_t = \sigma_t Z_t$ from 0 will tend to be large as well. Similarly, small deviations from 0 will tend to be followed by other small deviations. Thus a GARCH process will alternate between periods of big fluctuations and periods of small fluctuations. This is also expressed by saying that a GARCH process exhibits *volatility clustering*. Volatility clustering is commonly observed in time series of stock returns. The GARCH(1, 1) process has become a popular model for such time series. Figure 1.5 shows a realization. The signs of the X_t are equal to the signs of the Z_t and hence will be independent over time.

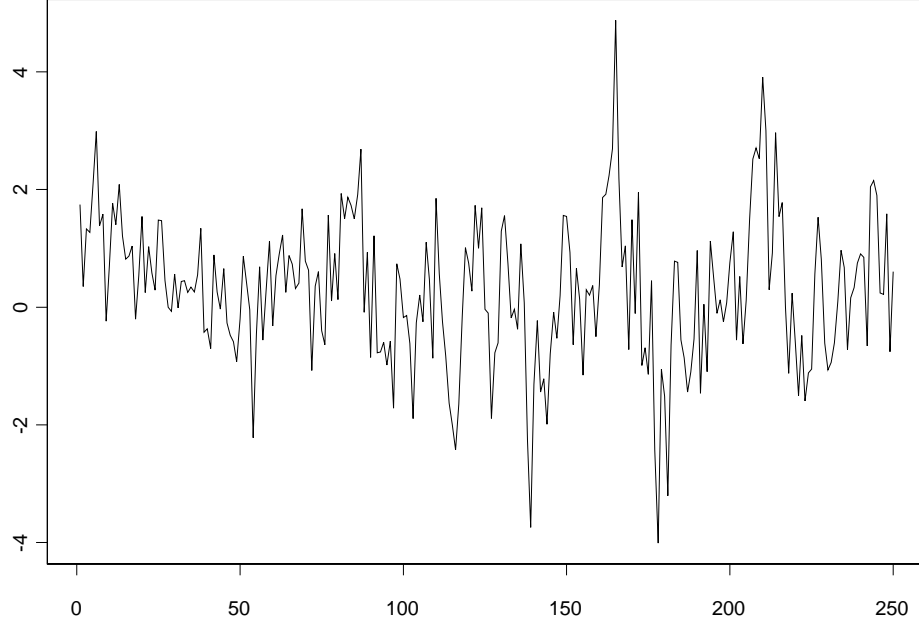

Figure 1.4. Realization of length 250 of the stationary solution to the equation $X_t = 0.5X_{t-1} + 0.2X_{t-2} + Z_t$ for Z_t Gaussian white noise.

The abbreviation GARCH is for “generalized auto-regressive conditional heteroscedasticity”: the conditional variances are not constant (not *homoscedastic*), and depend on the past through an auto-regressive scheme. Typically, the conditional variances σ_t^2 are not directly observed, but must be inferred from the observed sequence X_t .

Being a white noise process, a GARCH process can itself be used as input in another scheme, such as an auto-regressive or a moving average series, leading to e.g. AR-GARCH processes. There are also many generalizations of the GARCH structure. In a GARCH(p, q) process, the conditional variances σ_t^2 are allowed to depend on $\sigma_{t-1}^2, \dots, \sigma_{t-p}^2$ and $X_{t-1}^2, \dots, X_{t-q}^2$. A GARCH($0, q$) process is also called an ARCH process. The rationale of using the squares X_t^2 is that these are nonnegative and simple; there are many variations using other functions.

As the auto-regressive relationship, the defining GARCH equations are recursive, and it is not obvious that solutions to the pair of defining equations, and, if so, whether the solution is unique and satisfies (i)-(ii). If we are only interested in the process for $t \geq 0$, then we might complement the equations with an initial value for σ_0^2 , and solve the equations by iteration, taking a suitable sequence Z_t as given. Alternatively, we may study the existence of *stationary* solutions X_t to the equations.

We now show that there exists a stationary solution X_t to the GARCH equations if $\theta + \phi < 1$, which then is unique and automatically possesses the properties (i)-(ii). By iterating the GARCH relation we find that, for every $n \geq 0$,

$$\begin{aligned}\sigma_t^2 &= \alpha + (\phi + \theta Z_{t-1}^2)\sigma_{t-1}^2 = \alpha + \alpha \sum_{j=1}^n (\phi + \theta Z_{t-1}^2) \times \cdots \times (\phi + \theta Z_{t-j}^2) \\ &\quad + (\phi + \theta Z_{t-1}^2) \times \cdots \times (\phi + \theta Z_{t-n-1}^2)\sigma_{t-n-1}^2.\end{aligned}$$

The sequence $((\phi + \theta Z_{t-1}^2) \cdots (\phi + \theta Z_{t-n-1}^2))_{n=1}^\infty$, which consists of nonnegative variables with means $(\phi + \theta)^{n+1}$, converges in probability to zero if $\theta + \phi < 1$. If the time series σ_t^2 is bounded in probability as $t \rightarrow \infty$, then the term on the far right converges to zero in probability as $n \rightarrow \infty$. Thus for a stationary solution (X_t, σ_t) we must have

$$(1.2) \quad \sigma_t^2 = \alpha + \alpha \sum_{j=1}^\infty (\phi + \theta Z_{t-1}^2) \times \cdots \times (\phi + \theta Z_{t-j}^2).$$

This series has positive terms, and hence is always well defined. It is easily checked that the series converges in mean if and only if $\theta + \phi < 1$ (cf. Lemma 1.27). Given an i.i.d. series Z_t , we can then define a process X_t by first defining the conditional variances σ_t^2 by (1.2), and next setting $X_t = \sigma_t Z_t$. It can be verified by substitution that this process X_t solves the GARCH relationship (1.1). Hence a stationary solution to the GARCH equations exists if $\phi + \theta < 1$.

Because Z_t is independent of Z_{t-1}, Z_{t-2}, \dots , by (1.2) it is also independent of $\sigma_{t-1}^2, \sigma_{t-2}^2, \dots$, and hence also of $X_{t-1} = \sigma_{t-1} Z_{t-1}, X_{t-2} = \sigma_{t-2} Z_{t-2}, \dots$. This verifies property (ii). In addition it follows that the time series $X_t = \sigma_t Z_t$ is strictly stationary, being a fixed measurable transformation of (Z_t, Z_{t-1}, \dots) for every t .

By iterating the auto-regressive relation $\sigma_t^2 = \phi \sigma_{t-1}^2 + W_t$, with $W_t = \alpha + \theta X_{t-1}^2$, in the same way as in Example 1.8, we also find that for the stationary solution $\sigma_t^2 = \sum_{j=0}^\infty \phi^j W_{t-j}$. Hence σ_t is $\sigma(X_{t-1}, X_{t-2}, \dots)$ -measurable: property (i) is valid.

An inspection of the preceding argument shows that a *strictly* stationary solution exists under a weaker condition than $\phi + \theta < 1$. This is because the infinite series (1.2) may converge almost surely, without converging in mean (see Exercise 1.14). We shall study this further in Chapter 9. \square

1.11 EXERCISE. Let $\theta + \phi \in [0, 1)$ and $1 - \bar{\kappa}\theta^2 - \phi^2 - 2\theta\phi > 0$, where $\bar{\kappa} = \mathbb{E}Z_t^4$. Show that the second and fourth (marginal) moments of a stationary GARCH process are given by $\alpha/(1 - \theta - \phi)$ and $\bar{\kappa}\alpha^2(1 - (\theta + \phi)^2)/(1 - \bar{\kappa}\theta^2 - \phi^2 - 2\theta\phi)$. From this compute the kurtosis of the GARCH process with standard normal Z_t . [You can use (1.2), but it is easier to use the GARCH relations.]

1.12 EXERCISE. Show that $\mathbb{E}X_t^4 = \infty$ if $1 - \bar{\kappa}\theta^2 - \phi^2 - 2\theta\phi = 0$.

1.13 EXERCISE. Suppose that the process X_t is square-integrable and satisfies the GARCH relation for an i.i.d. sequence Z_t such that Z_t is independent of X_{t-1}, X_{t-2}, \dots and such that $\sigma_t^2 = \mathbb{E}(X_t^2 | X_{t-1}, X_{t-2}, \dots)$, for every t , and some $\alpha, \phi, \theta > 0$. Show that $\phi + \theta < 1$. [Derive that $\mathbb{E}X_t^2 = \alpha + \alpha \sum_{j=1}^n (\phi + \theta)^j + (\phi + \theta)^{n+1} \mathbb{E}X_{t-n-1}^2$.]

1.14 EXERCISE. Let Z_t be an i.i.d. sequence with $E\log(Z_t^2) < 0$. Show that $\sum_{j=0}^{\infty} Z_t^2 Z_{t-1}^2 \cdots Z_{t-j}^2 < \infty$ almost surely. [Use the Law of Large Numbers.]

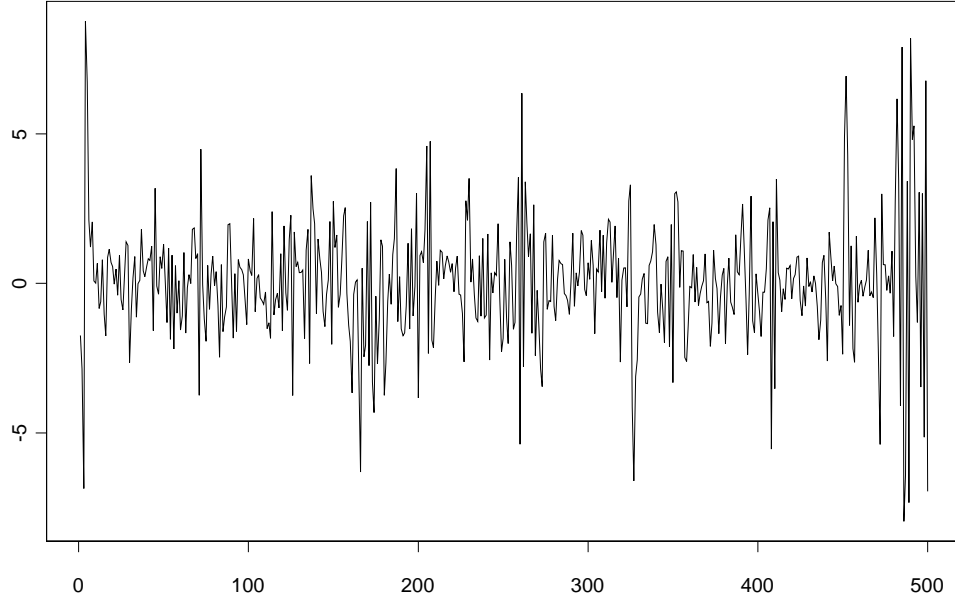

Figure 1.5. Realization of the GARCH(1,1) process with $\alpha = 0.1$, $\phi = 0$ and $\theta = 0.8$ of length 500 for Z_t Gaussian white noise.

1.15 Example (Stochastic volatility). A general approach to obtain a time series with volatility clustering is to define $X_t = \sigma_t Z_t$ for an i.i.d. sequence Z_t and a process σ_t that depends “positively on its past”. A GARCH model fits this scheme, but a simpler construction is to let σ_t depend only on its own past and independent noise. Because σ_t is to have an interpretation as a scale parameter, we restrain it to be positive. One way to combine these requirements is to set

$$\begin{aligned} h_t &= \theta h_{t-1} + W_t, \\ \sigma_t^2 &= e^{h_t}, \\ X_t &= \sigma_t Z_t. \end{aligned}$$

Here W_t is a white noise sequence, h_t is a (stationary) solution to the auto-regressive equation, and the process Z_t is i.i.d. and independent of the process W_t . If $\theta > 0$ and $\sigma_{t-1} = e^{h_{t-1}/2}$ is large, then $\sigma_t = e^{h_t/2}$ will tend to be large as well. Hence the process X_t will exhibit volatility clustering.

If $0 < \theta, 1$, then there exists a strictly stationary solution h_t , by Example 1.8, and the process X_t is also strictly stationary. Because there is no recursion between σ_t and X_t , existence of stationary versions is thus easily resolved, unlike for a GARCH series.

The process h_t will typically not be observed and for that reason is sometimes called *latent*. A “stochastic volatility process” of this type is an example of a (nonlinear) state space model, discussed in Chapter 10. Rather than defining σ_t by an auto-regression in the exponent, we may choose a different scheme. For instance, an EGARCH($p, 0$) model postulates the relationship

$$\log \sigma_t = \alpha + \sum_{j=1}^p \phi_j \log \sigma_{t-j}.$$

This is not a stochastic volatility model, because it does not include a random disturbance. The symmetric EGARCH (p, q) model repairs this by adding terms depending on the past of the observed series $X_t = \sigma_t Z_t$, giving

$$\log \sigma_t = \alpha + \sum_{j=1}^q \theta_j |Z_{t-j}| + \sum_{j=1}^p \phi_j \log \sigma_{t-j}.$$

This looks a bit GARCH like, and hence these processes their variants are much related to stochastic volatility models. In view of the recursive nature of the definitions of σ_t and X_t , they are perhaps more complicated. \square

1.2 Transformations and Filters

Many time series in real life are not stationary. Rather than modelling a nonstationary sequence, such a sequence is often transformed in a time series that is (assumed to be) stationary. The statistical analysis next focuses on the transformed series.

Two important deviations from stationarity are *trend* and *seasonality*. A trend is a long-term, steady increase or decrease in the general level of the time series. A seasonal component is a cyclic change in the level, the cycle length being for instance a year or a week. Even though Example 1.5 shows that a perfectly cyclic series can be modelled as a stationary series, it is often considered wise to remove such perfect cycles from a given series before applying statistical techniques.

There are many ways in which a given time series can be transformed into a series that is easier to analyse. Transforming individual variables X_t into variables $f(X_t)$ by a fixed function f (such as the logarithm) is a common technique to render the variables more stable. It does not transform a nonstationary series into a strictly stationary one, but it does change the autocovariance function, which may be a more useful summary for the transformed series. Another simple technique is *detrending* by subtracting a “best fitting polynomial in t ” of some fixed degree. This is commonly found by the method of

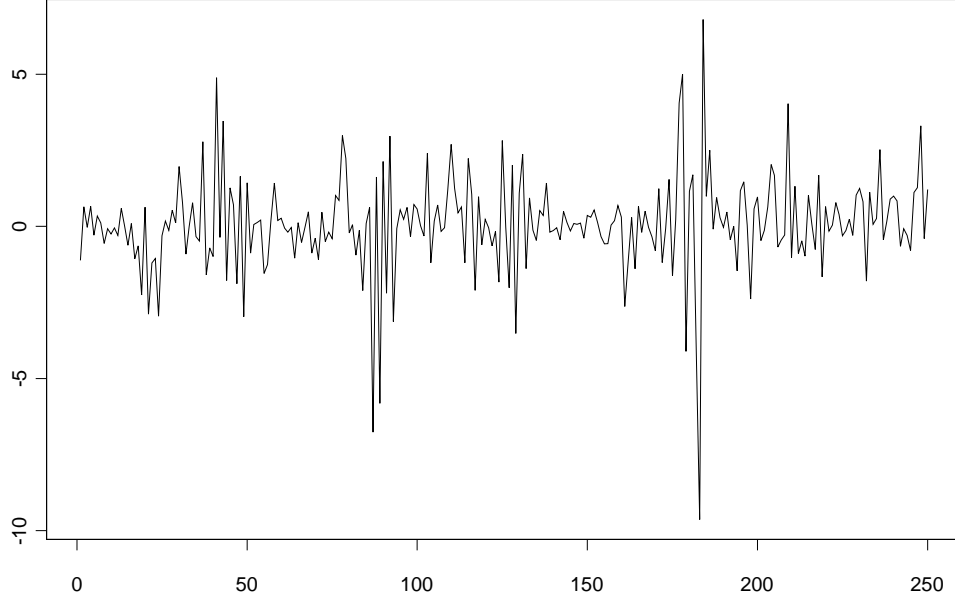

Figure 1.6. Realization of length 250 of the stochastic volatility model $X_t = e^{h_t/2}Z_t$ for a standard Gaussian i.i.d. process Z_t and a stationary auto-regressive process $h_t = 0.8h_{t-1} + W_t$ for a standard Gaussian i.i.d. process W_t .

least squares: given a nonstationary time series X_t we determine constants $\hat{\beta}_0, \dots, \hat{\beta}_p$ by minimizing

$$(\beta_0, \dots, \beta_p) \mapsto \sum_{t=1}^n (X_t - \beta_0 - \beta_1 t - \dots - \beta_p t^p)^2.$$

Next the time series $X_t - \hat{\beta}_0 - \hat{\beta}_1 t - \dots - \hat{\beta}_p t^p$ is assumed to be stationary.

A standard transformation for financial time series is to *(log) returns*, given by

$$\log \frac{X_t}{X_{t-1}}, \quad \text{or} \quad \frac{X_t}{X_{t-1}} - 1.$$

If X_t/X_{t-1} is close to unity for all t , then these transformations are similar, as $\log x \approx x - 1$ for $x \approx 1$. Because $\log(e^{ct}/e^{c(t-1)}) = c$, a log return can be intuitively interpreted as the exponent of exponential growth. Many financial time series exhibit an exponential trend, not always in the right direction for the owners of the corresponding assets.

A general method to transform a nonstationary sequence in a stationary one, advocated with much success in a famous book by Box and Jenkins, is *filtering*.

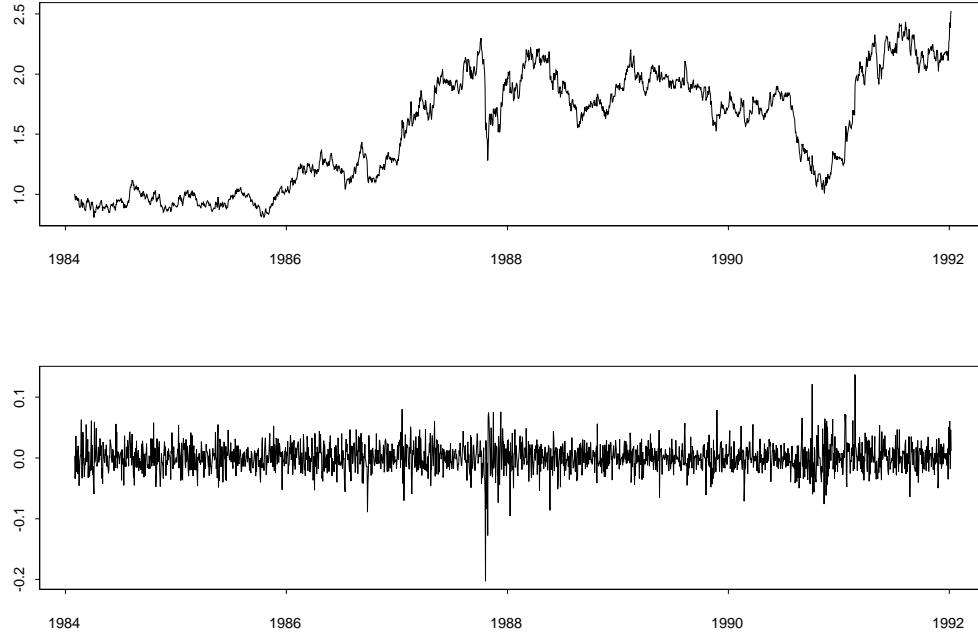

Figure 1.7. Prices of Hewlett Packard on New York Stock Exchange and corresponding log returns.

1.16 Definition. The (linear) filter with filter coefficients $(\psi_j: j \in \mathbb{Z})$ is the operation that transforms a given time series X_t into the time series $Y_t = \sum_{j \in \mathbb{Z}} \psi_j X_{t-j}$.

A linear filter is a moving average of infinite order. In Lemma 1.29 we give conditions for the infinite series to be well defined. All filters used in practice are *finite filters*: only finitely many coefficients ψ_j are nonzero. Important examples are the *difference filter*

$$\nabla X_t = X_t - X_{t-1},$$

and its repetitions $\nabla^k X_t = \nabla \nabla^{k-1} X_t$ defined recursively for $k = 2, 3, \dots$. Differencing with a bigger lag gives the *seasonal difference filter* $\nabla_k X_t = X_t - X_{t-k}$, for k the “length of the season” or “period”. It is intuitively clear that a time series may have stationary (seasonal) differences (or *increments*), but may itself be nonstationary.

1.17 Example (Polynomial trend). A linear trend model could take the form $X_t = at + Z_t$ for a strictly stationary time series Z_t . If $a \neq 0$, then the time series X_t is not stationary in the mean. However, the differenced series $\nabla X_t = a + Z_t - Z_{t-1}$ is stationary.

Thus differencing can be used to remove a linear trend. Similarly, a polynomial trend can be removed by repeated differencing: a polynomial trend of degree k is removed by applying ∇^k . \square

1.18 EXERCISE. Check this for a series of the form $X_t = at + bt^2 + Z_t$.

1.19 EXERCISE. Does a (repeated) seasonal filter also remove polynomial trend?

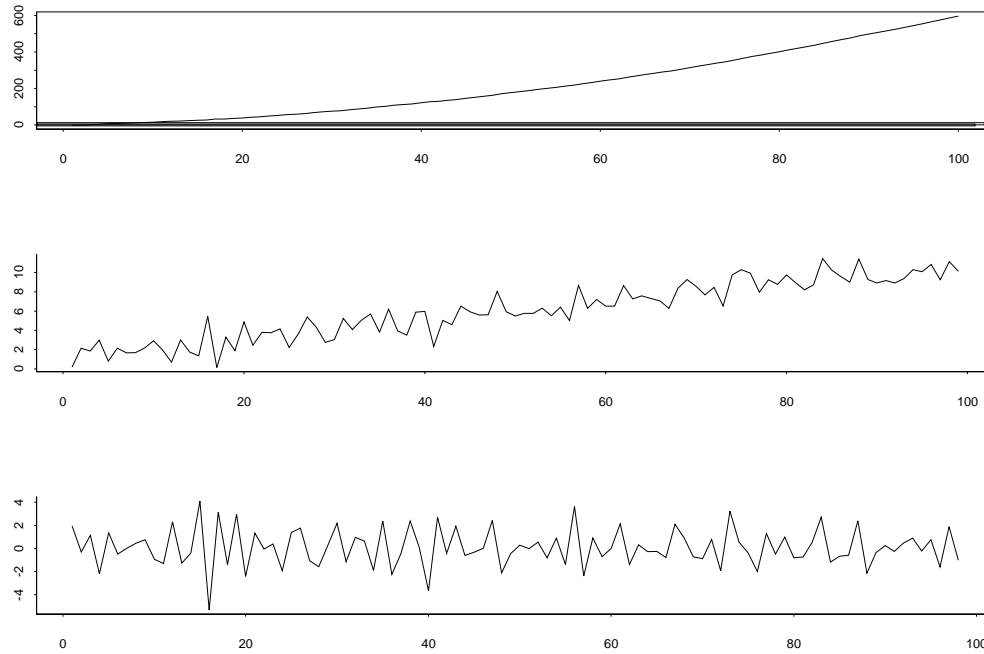

Figure 1.8. Realization of the time series $t + 0.05t^2 + X_t$ for the stationary auto-regressive process X_t satisfying $X_t - 0.8X_{t-1} = Z_t$ for Gaussian white noise Z_t , and the same series after once and twice differencing.

1.20 Example (Random walk). A *random walk* is defined as the sequence of partial sums $X_t = Z_1 + Z_2 + \cdots + Z_t$ of an i.i.d. sequence Z_t (with $X_0 = 0$). A random walk is not stationary, but the differenced series $\nabla X_t = Z_t$ certainly is. \square

1.21 Example (Monthly cycle). If X_t is the value of a system in month t , then $\nabla_{12} X_t$ is the change in the system during the past year. For seasonable variables without trend this series might be modelled as stationary. For series that contain both yearly seasonality and polynomial trend, the series $\nabla^k \nabla_{12} X_t$ might be stationary. \square

1.22 Example (Weekly averages). If X_t is the value of a system at day t , then $Y_t = (1/7) \sum_{j=0}^6 X_{t-j}$ is the average value over the last week. This series might show trend, but should not show seasonality due to day-of-the-week. We could study seasonality by considering the time series $X_t - Y_t$, which results from filtering the series X_t with coefficients $(\psi_0, \dots, \psi_6) = (6/7, -1/7, \dots, -1/7)$. \square

1.23 Example (Exponential smoothing). An ad-hoc method for predicting the future is to equate the future to the present or, more generally, to the average of the last k observed values of a time series. When averaging past values it is natural to give more weight to the most recent values. Exponentially decreasing weights appear to have some popularity. This corresponds to predicting a future value of a time series X_t by the weighted average $\sum_{j=0}^{\infty} \theta^j (1 - \theta)^{-1} X_{t-j}$ for some $\theta \in (0, 1)$. The coefficients $\psi_j = \theta^j / (1 - \theta)$ of this filter decrease exponentially and satisfy $\sum \psi_j = 1$. \square

1.24 EXERCISE (Convolution). Show that the result of two filters with coefficients α_j and β_j applied in turn (if well defined) is the filter with coefficients γ_j given by $\gamma_k = \sum_j \alpha_j \beta_{k-j}$. This is called the *convolution* of the two filters. Infer that filtering is commutative.

1.25 Definition. A filter with coefficients ψ_j is *causal* if $\psi_j = 0$ for every $j < 0$.

For a causal filter the variable $Y_t = \sum_j \psi_j X_{t-j}$ depends only on the values X_t, X_{t-1}, \dots of the original time series in the present and past, not the future. This is important for prediction. Given X_t up to some time t , we can calculate Y_t up to time t . If Y_t is stationary, we can use results for stationary time series to predict the future value Y_{t+1} . Next we predict the future value X_{t+1} by $X_{t+1} = \psi_0^{-1} (Y_{t+1} - \sum_{j>0} \psi_j X_{t+1-j})$.

1.2.1 Convergence of random series

In order to derive conditions that guarantee that an infinite filter is well defined, we start with a lemma concerning series of random variables. Recall that a series $\sum_t x_t$ of nonnegative numbers is always well defined (although possibly ∞), where the order of summation is irrelevant. Furthermore, for general numbers x_t the absolute convergence $\sum_t |x_t| < \infty$ implies that $\sum_t x_t$ exists as a finite number, where the order of summation is again irrelevant. We shall be concerned with series indexed by t belonging to some countable set T , such as \mathbb{N} , \mathbb{Z} , or \mathbb{Z}^2 . It follows from the preceding that $\sum_{t \in T} x_t$ is well defined as a limit as $n \rightarrow \infty$ of partial sums $\sum_{t \in T_n} x_t$, for any increasing sequence of finite subsets $T_n \subset T$ with union T , if either every x_t is nonnegative or $\sum_t |x_t| < \infty$. For instance, in the case that the index set T is equal to \mathbb{Z} , we can choose the sets $T_n = \{t \in \mathbb{Z} : |t| \leq n\}$.

1.26 Definition. A series $\sum_t X_t$ converges in p th mean if there is a random variable Y such that $Y_n := \sum_{t \in T_n} X_t \rightarrow Y$ in p th mean: $E|Y_n - Y|^p \rightarrow 0$. The limit Y is then denoted $\sum_t X_t$. For $p = 1$ and $p = 2$ we say *convergence in mean* and *convergence in second mean*, or, alternatively, “convergence in quadratic mean” or “convergence in L_1 or L_2 ”.

1.27 Lemma. Let $(X_t : t \in T)$ be an arbitrary countable set of random variables.

- (i) If $X_t \geq 0$ for every t , then $E \sum_t X_t = \sum_t E X_t$ (possibly $+\infty$);
- (ii) If $\sum_t E|X_t| < \infty$, then the series $\sum_t X_t$ converges absolutely almost surely and in mean, and $E \sum_t X_t = \sum_t E X_t$.

Proof. Suppose $T = \cup_j T_j$ for an increasing sequence $T_1 \subset T_2 \subset \dots$ of finite subsets of T . Assertion (i) follows from the monotone convergence theorem applied to the variables $Y_j = \sum_{t \in T_j} X_t$. For the proof of (ii) we first note that $Z = \sum_t |X_t|$ is well defined, with finite mean $EZ = \sum_t E|X_t|$, by (i). Thus $\sum_t |X_t|$ converges almost surely to a finite limit, and hence $Y := \sum_t X_t$ converges almost surely as well. The variables $Y_j = \sum_{t \in T_j} X_t$ are dominated by Z and converge to Y as $j \rightarrow \infty$. Hence $EY_j \rightarrow EY$ by the dominated convergence theorem. ■

1.28 EXERCISE. Suppose that $E|X_n - X|^p \rightarrow 0$ and $E|X|^p < \infty$ for some $p \geq 1$. Show that $EX_n^k \rightarrow EX^k$ for every $0 < k \leq p$.

1.29 Lemma (Filtering). Let $(Z_t: t \in \mathbb{Z})$ be an arbitrary time series and let $\sum_j |\psi_j| < \infty$.

- (i) If $\sup_t E|Z_t| < \infty$, then $\sum_j \psi_j Z_{t-j}$ converges absolutely, almost surely and in mean.
- (ii) If $\sup_t E|Z_t|^2 < \infty$, then $\sum_j \psi_j Z_{t-j}$ converges in second mean as well.
- (iii) If the series Z_t is stationary, then so is the series $X_t = \sum_j \psi_j Z_{t-j}$ and $\gamma_X(h) = \sum_l \sum_j \psi_j \psi_{j+l-h} \gamma_Z(l)$.

Proof. (i). Because $\sum_t E|\psi_j Z_{t-j}| \leq \sup_t E|Z_t| \sum_j |\psi_j| < \infty$, it follows by (ii) of the preceding lemma that the series $\sum_j \psi_j Z_{t-j}$ is absolutely convergent, almost surely. The convergence in mean follows as in the remark following the lemma.

(ii). By (i) the series converges almost surely, and $\sum_j \psi_j Z_{t-j} - \sum_{|j| \leq k} \psi_j Z_{t-j} = \sum_{|j| > k} \psi_j Z_{t-j}$. By the triangle inequality we have

$$\left| \sum_{|j| > k} \psi_j Z_{t-j} \right|^2 \leq \left(\sum_{|j| > k} |\psi_j Z_{t-j}| \right)^2 = \sum_{|j| > k} \sum_{|i| > k} |\psi_j| |\psi_i| |Z_{t-j}| |Z_{t-i}|.$$

By the Cauchy-Schwarz inequality $E|Z_{t-j}| |Z_{t-i}| \leq (E|Z_{t-j}|^2 E|Z_{t-i}|^2)^{1/2}$, which is bounded by $\sup_t E|Z_t|^2$. Therefore, in view of (i) of the preceding lemma the expectation of the right side (and hence the left side) of the preceding display is bounded above by

$$\sum_{|j| > k} \sum_{|i| > k} |\psi_j| |\psi_i| \sup_t E|Z_t|^2 = \left(\sum_{|j| > k} |\psi_j| \right)^2 \sup_t E|Z_t|^2.$$

This converges to zero as $k \rightarrow \infty$.

(iii). By (i) the series $\sum_j \psi_j Z_{t-j}$ converges in mean. Therefore, $E \sum_j \psi_j Z_{t-j} = \sum_j \psi_j E Z_t$, which is independent of t . Using arguments as under (ii), we see that we can also justify the interchange of the order of expectations (hidden in the covariance) and double sums in

$$\begin{aligned} \gamma_X(h) &= \text{cov} \left(\sum_j \psi_j Z_{t+h-j}, \sum_i \psi_i Z_{t-i} \right) \\ &= \sum_j \sum_i \psi_j \psi_i \text{cov}(Z_{t+h-j}, Z_{t-i}) = \sum_j \sum_i \psi_j \psi_i \gamma_Z(h-j+i). \end{aligned}$$

This can be written in the form given by the lemma by the change of variables $(j, i) \mapsto (j, j+l-h)$. ■

1.30 EXERCISE. Suppose that the series Z_t in (iii) is strictly stationary. Show that the series X_t is strictly stationary whenever it is well defined. [You need measure theory to make the argument mathematically rigorous(?).]

* **1.31 EXERCISE.** For a white noise series Z_t , part (ii) of the preceding lemma can be improved: Suppose that Z_t is a white noise sequence and $\sum_j \psi_j^2 < \infty$. Show that $\sum_j \psi_j Z_{t-j}$ converges in second mean. [For this exercise you may want to use material from Chapter 2.]

1.3 Complex Random Variables

Even though no real-life time series is complex valued, the use of complex numbers is notationally convenient to develop the mathematical theory. In this section we discuss complex-valued random variables.

A *complex random variable* Z is a map from some probability space into the field of complex numbers whose real and imaginary parts are random variables. For complex random variables $Z = X + iY$, Z_1 and Z_2 , we define

$$\begin{aligned} EZ &= EX + iEY, \\ \text{var } Z &= E|Z - EZ|^2, \\ \text{cov}(Z_1, Z_2) &= E(Z_1 - EZ_1)(\overline{Z_2 - EZ_2}). \end{aligned}$$

Here the overbar means *complex conjugation*. Some simple properties are, for $\alpha, \beta \in \mathbb{C}$,

$$\begin{aligned} E\alpha Z &= \alpha EZ, & E\overline{Z} &= \overline{EZ}, \\ \text{var } Z &= E|Z|^2 - |EZ|^2 = \text{var } X + \text{var } Y = \text{cov}(Z, Z), \\ \text{var}(\alpha Z) &= |\alpha|^2 \text{var } Z, \\ \text{cov}(\alpha Z_1, \beta Z_2) &= \alpha\overline{\beta} \text{cov}(Z_1, Z_2), \\ \text{cov}(Z_1, Z_2) &= \overline{\text{cov}(Z_2, Z_1)} = EZ_1\overline{Z_2} - EZ_1EZ_2. \end{aligned}$$

A *complex random vector* is of course a vector $Z = (Z_1, \dots, Z_n)^T$ of complex random variables Z_i defined on the same probability space. Its covariance matrix $\text{Cov}(Z)$ is the $(n \times n)$ matrix of covariances $\text{cov}(Z_i, Z_j)$.

1.32 EXERCISE. Prove the preceding identities.

1.33 EXERCISE. Prove that a covariance matrix $\Sigma = \text{Cov}(Z)$ of a complex random vector Z is *Hermitian* (i.e. $\overline{\Sigma} = \Sigma^T$) and *nonnegative-definite* (i.e. $\alpha\Sigma\overline{\alpha}^T \geq 0$ for every $\alpha \in \mathbb{C}^n$). Here Σ^T is the reflection of a matrix, defined to have (i, j) -element $\Sigma_{j,i}$.

A *complex time series* is a (doubly infinite) sequence of complex-valued random variables X_t . The definitions of mean, covariance function, and (strict) stationarity given

for real time series apply equally well to complex time series. In particular, the auto-covariance function of a stationary complex time series is the function $\gamma_X: \mathbb{Z} \rightarrow \mathbb{C}$ defined by $\gamma_X(h) = \text{cov}(X_{t+h}, X_t)$. Lemma 1.29 also extends to complex time series Z_t , where in (iii) we must read $\gamma_X(h) = \sum_l \sum_j \psi_j \bar{\psi}_{j+l-h} \gamma_Z(l)$.

1.34 EXERCISE. Show that the auto-covariance function of a complex stationary time series X_t is conjugate symmetric: $\gamma_X(-h) = \bar{\gamma_X(h)}$, for every $h \in \mathbb{Z}$. (The positions of X_{t+h} and X_t in the definition $\gamma_X(h) = \text{cov}(X_{t+h}, X_t)$ matter!)

Useful as these definitions are, it should be noted that the second-order structure of a complex-valued time series is only partly described by its covariance function. A complex random variable is geometrically equivalent to the two-dimensional real vector of its real and imaginary parts. More generally, a complex random vector $Z = (Z_1, \dots, Z_n)^T$ of dimension n can be identified with the $2n$ -dimensional real vector that combines all real and imaginary parts. The second order structure of the latter vector is determined by a $2n$ -dimensional real covariance matrix, and this is not completely determined by the $(n \times n)$ complex covariance matrix of Z . This is clear from comparing the dimensions of these objects. For instance, for $n = 1$ the complex covariance matrix of Z is simply the single positive number $\text{var } Z$, whereas the covariance matrix of its pair of real and imaginary parts is a symmetric (2×2) -matrix. This discrepancy increases with n . The covariance matrix of a complex vector of dimension n contains n reals on the diagonal and $\frac{1}{2}n(n-1)$ complex numbers off the diagonal, giving $n + n(n-1) = n^2$ reals in total, whereas a real covariance matrix of dimension $2n$ varies over an open set of $\frac{1}{2}2n(2n+1)$ reals.

* 1.3.1 Complex Gaussian vectors

It is particularly important to keep this in mind when working with complex Gaussian vectors. A complex random vector $Z = (Z_1, \dots, Z_n)$ is *normally distributed* or *Gaussian* if the $2n$ -vector of all its real and imaginary parts is multivariate-normally distributed. The latter distribution is determined by the mean vector and the covariance matrix of the latter $2n$ -vector. The mean vector is one-to-one related to the (complex) mean vector of Z , but the complex covariances $\text{cov}(Z_i, Z_j)$ do not completely determine the covariance matrix of the combined real and imaginary parts. This is sometimes resolved by requiring that the covariance matrix of the $2n$ -vector has the special form

$$(1.3) \quad \frac{1}{2} \begin{pmatrix} \text{Re } \Sigma & -\text{Im } \Sigma \\ \text{Im } \Sigma & \text{Re } \Sigma \end{pmatrix}.$$

Here $\text{Re } \Sigma$ and $\text{Im } \Sigma$ are the real and imaginary parts of the complex covariance matrix $\Sigma = \text{Re } \Sigma + i \text{Im } \Sigma$ of Z . A Gaussian distribution with covariance matrix of this type is sometimes called *circular complex normal*. This distribution is completely described by the mean vector μ and covariance matrix Σ , and can be referred to by a code such as $N_n(\mu, \Sigma)$. However, the additional requirement (1.3) imposes a relationship between the vectors of real and imaginary parts of Z , which seems not natural for a general definition of a Gaussian complex vector. For instance, under the requirement (1.3) a

complex Gaussian variable Z (for $n = 1$) would be equivalent to a pair of *independent* real Gaussian variables each with variance equal to $\frac{1}{2} \text{var } Z$.

On the other hand, the covariance matrix of any complex vector that can be constructed by linearly transforming total *complex white noise* is of the form (1.3). Here by “total complex white noise” we mean a complex vector of the form $U + iV$, with $(U^T, V^T)^T$ a $2n$ -real vector with covariance matrix $\frac{1}{2}$ times the identity. The covariance matrix of the real and imaginary parts of the complex vector $A(U + iV)$ is then of the form (1.3), for any complex matrix A (see Problem 1.36). Furthermore, the “canonical construction” of a complex vector Z with prescribed covariance matrix Σ , using the spectral decomposition, also yields real and imaginary parts with covariance matrix (1.3) (see Problem 1.37), and the coordinates of a complex $N(\mu, \Sigma)$ -vector are independent if and only if Σ is diagonal.

Warning. If X is a real Gaussian n -vector and A a complex matrix, then AX is not necessarily a complex Gaussian vector, if the definition of the latter concept includes the requirement that the covariance matrix of the vector of real and imaginary parts takes the form (1.3).

1.35 Example (Complex trigonometric series). The time series $X_t = Ae^{it\lambda}$, for a complex-valued random variable A and a fixed real number λ , defines a complex version of the trigonometric time series considered in Example 1.5. If $EA = 0$ and $\text{var } A = \sigma^2$ is finite, then this time series is stationary with mean 0 and autocovariances $\gamma_X(h) = \sigma^2 e^{ih\lambda}$.

The real part $\text{Re } X_t$ of this time series takes the form of the series in Example 1.5, with the variables A and B in that example taken equal to $\text{Re } A$ and $\text{Im } A$. It follows that the real part is stationary if $\text{Re } A$ and $\text{Im } A$ have equal variance and are uncorrelated, i.e. if the covariance of A has the form (1.3). If this is not the case, then the real part will typically not be stationary. For instance, in the case that the variances of $\text{Re } A$ and $\text{Im } A$ are equal, the extra term $E \text{Re } A \text{Im } A \cos((t+h)\lambda) \sin(t\lambda)$ will appear in the formula for the covariance of $\text{Re } X_{t+h}$ and $\text{Re } X_t$, which depends on h unless $E \text{Re } A \text{Im } A = 0$.

Thus a stationary complex time series may have nonstationary real and imaginary parts! \square

1.36 EXERCISE. Let U and V be real n -vectors with $EUU^T = EVV^T = I$ and $EUV^T = 0$. Show that for any complex $(n \times n)$ -matrix A the complex vector $A(U + iV)$ possesses covariance matrix of the form (1.3).

1.37 EXERCISE. A nonnegative, Hermitian complex matrix Σ can be decomposed as $\Sigma = OD\bar{O}^T$ for a unitary matrix O and a real diagonal matrix D . Given uncorrelated real vectors U and V each with mean zero and covariance matrix $\frac{1}{2}I$ set $Z = O\sqrt{D}(U + iV)$.

(i) Show that $\text{Cov } Z = \Sigma$.

(ii) Show that $(\text{Re } Z, \text{Im } Z)$ possesses covariance matrix (1.3).

(If $O\sqrt{D} = A + iB$, then $\Sigma = O\sqrt{D}(\bar{O}\sqrt{D})^T = (A + iB)(A^T - iB^T)$, whence $\text{Re } \Sigma = AA^T + BB^T$ and $\text{Im } \Sigma = BA^T - AB^T$. Also $Z = AU - BV + i(AV + BU)$.)

1.38 EXERCISE. Suppose that the $2n$ -vector $(X^T, Y^T)^T$ possesses covariance matrix

as (1.3). Show that the n -vector $Z = X + iY$ possesses covariance matrix Σ . Also show that $E(Z - EZ)(Z - EZ)^T = 0$.

1.39 EXERCISE. Let Z and \tilde{Z} be independent complex random vectors with mean zero and covariance matrix Σ .

- (i) Show that $E(\operatorname{Re} Z)(\operatorname{Re} Z)^T + E(\operatorname{Im} Z)(\operatorname{Im} Z)^T = \operatorname{Re} \Sigma$ and $E(\operatorname{Im} Z)(\operatorname{Re} Z)^T - E(\operatorname{Re} Z)(\operatorname{Im} Z)^T = \operatorname{Im} \Sigma$.
- (ii) Show that the $2n$ -vector $(X^T, Y^T)^T$ defined by $X = (\operatorname{Re} Z + \operatorname{Im} \tilde{Z})/\sqrt{2}$ and $Y = (-\operatorname{Re} \tilde{Z} + \operatorname{Im} Z)/\sqrt{2}$ possesses covariance matrix (1.3).
- (iii) Show that the $2n$ -vector $(\operatorname{Re} Z^T, \operatorname{Im} Z^T)^T$ does not necessarily have this property.

1.40 EXERCISE. Say that a complex n -vector $Z = X + iY$ is $N_n(\mu, \Sigma)$ distributed if the $2n$ real vector $(X^T, Y^T)^T$ is multivariate normally distributed with mean $(\operatorname{Re} \mu, \operatorname{Im} \mu)$ and covariance matrix (1.3). Show that:

- (i) If Z is $N(\mu, \Sigma)$ -distributed, then $AZ + b$ is $N(A\mu + b, A\Sigma A^T)$ -distributed.
- (ii) If Z_1 and Z_2 are independent and $N(\mu_i, \Sigma_i)$ -distributed, then $Z_1 + Z_2$ is $N(\mu_1 + \mu_2, \Sigma_1 + \Sigma_2)$ -distributed.
- (iii) If X is a real vector and $N(\mu, \Sigma)$ -distributed and A is a complex matrix, then AX is typically *not* complex normally distributed.

1.4 Multivariate Time Series

In many applications we are interested in the time evolution of several variables jointly. This can be modelled through vector-valued time series. The definition of a stationary time series applies without changes to vector-valued series $X_t = (X_{t,1}, \dots, X_{t,d})^T$. Here the mean EX_t is understood to be the vector $(EX_{t,1}, \dots, EX_{t,d})^T$ of means of the coordinates and the *auto-covariance function* is defined to be the matrix

$$\gamma_X(h) = \left(\operatorname{cov}(X_{t+h,i}, X_{t,j}) \right)_{i,j=1,\dots,d} = E(X_{t+h} - EX_{t+h})(\overline{X_t - EX_t})^T.$$

The *auto-correlation* at lag h is defined as

$$\rho_X(h) = \left(\rho(X_{t+h,i}, X_{t,j}) \right)_{i,j=1,\dots,d} = \operatorname{diag}(\sqrt{\gamma_X(0)}) \gamma_X(h) \operatorname{diag}(\sqrt{\gamma_X(0)}).$$

The study of properties of multivariate time series can often be reduced to the study of univariate time series by taking linear combinations $\alpha^T X_t$ of the coordinates. The first and second moments satisfy, for every $\alpha \in \mathbb{C}^n$,

$$E\alpha^T X_t = \alpha^T EX_t, \quad \gamma_{\alpha^T X}(h) = \alpha^T \gamma_X(h) \bar{\alpha}.$$

1.41 EXERCISE. Show that the auto-covariance function of a complex, multivariate, stationary time series X satisfies $\gamma_X(h)^T = \overline{\gamma_X(-h)}$, for every $h \in \mathbb{Z}$. (The order of the two random variables in the definition $\gamma_X(h) = \operatorname{cov}(X_{t+h}, X_t)$ matters!)

2

Hilbert Spaces and Prediction

In this chapter we first recall definitions and basic facts concerning Hilbert spaces. In particular, we consider the Hilbert space of square-integrable random variables, with the covariance as the inner product. Next we apply the Hilbert space theory to solve the *prediction problem*: finding the “best” predictor of X_{n+1} , or other future variables, based on observations X_1, \dots, X_n .

2.1 Hilbert Spaces and Projections

Given a measure space $(\Omega, \mathcal{U}, \mu)$, we define $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ (or $\mathcal{L}_2(\mu)$ for short) as the set of all measurable functions $f: \Omega \rightarrow \mathbb{C}$ such that $\int |f|^2 d\mu < \infty$. (Alternatively, all measurable functions with values in \mathbb{R} with this property.) Here a complex-valued function is said to be *measurable* if both its real and imaginary parts $\operatorname{Re} f$ and $\operatorname{Im} f$ are measurable functions. Its integral is by definition

$$\int f d\mu = \int \operatorname{Re} f d\mu + i \int \operatorname{Im} f d\mu,$$

provided the two integrals on the right are defined and finite. We set

$$\begin{aligned} \langle f_1, f_2 \rangle &= \int f_1 \bar{f}_2 d\mu, \\ \|f\| &= \sqrt{\int |f|^2 d\mu}, \\ d(f_1, f_2) &= \|f_1 - f_2\| = \sqrt{\int |f_1 - f_2|^2 d\mu}. \end{aligned} \tag{2.1}$$

These define a semi-inner product, a semi-norm, and a semi-metric, respectively. The first is a *semi-inner product* in view of the properties:

$$\begin{aligned}\langle f_1 + f_2, f_3 \rangle &= \langle f_1, f_3 \rangle + \langle f_2, f_3 \rangle, \\ \langle \alpha f_1, \beta f_2 \rangle &= \alpha \bar{\beta} \langle f_1, f_2 \rangle, \\ \langle f_2, f_1 \rangle &= \overline{\langle f_1, f_2 \rangle}, \\ \langle f, f \rangle &\geq 0, \quad \text{with equality iff } f = 0, \text{ a.e.}\end{aligned}$$

These equalities are immediate consequences of the definitions, and the linearity of the integral.

The second entity in (2.1) is a *semi-norm* because it has the properties:

$$\begin{aligned}\|f_1 + f_2\| &\leq \|f_1\| + \|f_2\|, \\ \|\alpha f\| &= |\alpha| \|f\|, \\ \|f\| &= 0 \quad \text{iff } f = 0, \text{ a.e.}\end{aligned}$$

Here the first line, the *triangle inequality* is not immediate, but it can be proved with the help of the Cauchy-Schwarz inequality, given below. The other properties are obvious.

The third object in (2.1) is a *semi-distance*, in view of the relations:

$$\begin{aligned}d(f_1, f_3) &\leq d(f_1, f_2) + d(f_2, f_3), \\ d(f_1, f_2) &= d(f_2, f_1), \\ d(f_1, f_2) &= 0 \text{ iff } f_1 = f_2, \text{ a.e.}\end{aligned}$$

The first property is again a *triangle inequality*, and follows from the corresponding inequality for the norm.

Immediate consequences of the definitions and the properties of the inner product are

$$\begin{aligned}(2.2) \quad \|f + g\|^2 &= \langle f + g, f + g \rangle = \|f\|^2 + 2 \operatorname{Re} \langle f, g \rangle + \|g\|^2, \\ \|f + g\|^2 &= \|f\|^2 + \|g\|^2, \quad \text{if } \langle f, g \rangle = 0.\end{aligned}$$

The last equality is *Pythagoras' rule*. In the complex case this is true, more generally, for functions f, g with $\operatorname{Re} \langle f, g \rangle = 0$, as is immediate from the first equality.

2.1 Lemma (Cauchy-Schwarz). Any pair f, g in $L_2(\Omega, \mathcal{U}, \mu)$ satisfies $|\langle f, g \rangle| \leq \|f\| \|g\|$.

Proof. This follows upon working out the inequality $\|f - \lambda g\|^2 \geq 0$ for $\lambda = \langle f, g \rangle / \|g\|^2$ using the decomposition (2.2). ■

Now the triangle inequality for the norm follows from the decomposition (2.2) and the Cauchy-Schwarz inequality, which, when combined, yield

$$\|f + g\|^2 \leq \|f\|^2 + 2\|f\| \|g\| + \|g\|^2 = (\|f\| + \|g\|)^2.$$

Another consequence of the Cauchy-Schwarz inequality is the *continuity of the inner product*:

$$(2.3) \quad f_n \rightarrow f, g_n \rightarrow g \text{ implies that } \langle f_n, g_n \rangle \rightarrow \langle f, g \rangle.$$

2.2 EXERCISE. Prove this.

2.3 EXERCISE. Prove that $|\|f\| - \|g\|| \leq \|f - g\|$.

2.4 EXERCISE. Derive the *parallelogram rule*: $\|f + g\|^2 + \|f - g\|^2 = 2\|f\|^2 + 2\|g\|^2$.

2.5 EXERCISE. Prove that $\|f + ig\|^2 = \|f\|^2 + \|g\|^2$ for every pair f, g of real functions in $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$.

2.6 EXERCISE. Let $\Omega = \{1, 2, \dots, k\}$, $\mathcal{U} = 2^\Omega$ the power set of Ω and μ the counting measure on Ω . Show that $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ is exactly \mathbb{C}^k (or \mathbb{R}^k in the real case).

We attached the qualifier “semi” to the inner product, norm and distance defined previously, because in every of the three cases, the third of the three properties involves a null set. For instance $\|f\| = 0$ does not imply that $f = 0$, but only that $f = 0$ almost everywhere. If we think of two functions that are equal almost everywhere as the same “function”, then we obtain a true inner product, norm and distance. We define $L_2(\Omega, \mathcal{U}, \mu)$ as the set of all equivalence classes in $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ under the equivalence relation “ $f \equiv g$ if and only if $f = g$ almost everywhere”. It is a common abuse of terminology, which we adopt as well, to refer to the equivalence classes as “functions”.

2.7 Proposition. *The metric space $L_2(\Omega, \mathcal{U}, \mu)$ is complete under the metric d .*

We shall need this proposition only occasionally, and do not provide a proof. (See e.g. Rudin, Theorem 3.11.) The proposition asserts that for every sequence f_n of functions in $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ such that $\int |f_n - f_m|^2 d\mu \rightarrow 0$ as $m, n \rightarrow \infty$ (a *Cauchy sequence*), there exists a function $f \in \mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ such that $\int |f_n - f|^2 d\mu \rightarrow 0$ as $n \rightarrow \infty$.

2.8 Definition. *A Hilbert space is a set equipped with an inner product that is metrically complete under the corresponding metric.*

The space $L_2(\Omega, \mathcal{U}, \mu)$ is an example of an Hilbert space, and the only example we need. (In fact, this is not a great loss of generality, because it can be proved that any Hilbert space is (isometrically) isomorphic to a space $L_2(\Omega, \mathcal{U}, \mu)$ for some $(\Omega, \mathcal{U}, \mu)$.)

2.9 Definition. *Two elements f, g of $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ are orthogonal if $\langle f, g \rangle = 0$. This is denoted $f \perp g$. Two subsets \mathcal{F}, \mathcal{G} of $\mathcal{L}_2(\Omega, \mathcal{U}, \mu)$ are orthogonal if $f \perp g$ for every $f \in \mathcal{F}$ and $g \in \mathcal{G}$. This is denoted $\mathcal{F} \perp \mathcal{G}$.*

2.10 EXERCISE. If $f \perp \mathcal{G}$ for some subset $\mathcal{G} \subset \mathcal{L}_2(\Omega, \mathcal{U}, \mu)$, show that $f \perp \overline{\text{lin } \mathcal{G}}$, where $\overline{\text{lin } \mathcal{G}}$ is the closure of the *linear span* $\text{lin } \mathcal{G}$ of \mathcal{G} . (The *linear span* of a set is the set of all finite linear combinations of elements of the set.)

2.11 Theorem (Projection theorem). *Let $L \subset L_2(\Omega, \mathcal{U}, \mu)$ be a closed linear subspace. For every $f \in L_2(\Omega, \mathcal{U}, \mu)$ there exists a unique element $\Pi f \in L$ that minimizes $l \mapsto \|f - l\|^2$ over $l \in L$. This element is uniquely determined by the requirements $\Pi f \in L$ and $f - \Pi f \perp L$.*

Proof. Let $d = \inf_{l \in L} \|f - l\|$ be the “minimal” distance of f to L . This is finite, because $0 \in L$ and $\|f\| < \infty$. Let l_n be a sequence in L such that $\|f - l_n\|^2 \rightarrow d$. By the parallelogram law

$$\begin{aligned} \|(l_m - f) + (f - l_n)\|^2 &= 2\|l_m - f\|^2 + 2\|f - l_n\|^2 - \|(l_m - f) - (f - l_n)\|^2 \\ &= 2\|l_m - f\|^2 + 2\|f - l_n\|^2 - 4\left\|\frac{1}{2}(l_m + l_n) - f\right\|^2. \end{aligned}$$

The two first terms on the far right both converge to $2d^2$ as $m, n \rightarrow \infty$. Because $(l_m + l_n)/2 \in L$, the last term on the far right is bounded above by $-4d^2$. We conclude that the left side, which is $\|l_m - l_n\|^2$, is bounded above by $2d^2 + 2d^2 + o(1) - 4d^2 = o(1)$ and hence, being nonnegative, converges to zero. Thus l_n is a Cauchy sequence, and has a limit l , by the completeness of $L_2(\Omega, \mathcal{U}, \mu)$. The limit is in L , because L is closed. By the continuity of the norm $\|f - l\| = \lim \|f - l_n\| = d$. Thus the limit l qualifies as the minimizing element Πf .

If both $\Pi_1 f$ and $\Pi_2 f$ are candidates for Πf , then we can take the sequence l_1, l_2, l_3, \dots in the preceding argument equal to the sequence $\Pi_1 f, \Pi_2 f, \Pi_1 f, \dots$. It then follows that this sequence is a Cauchy-sequence and hence converges to a limit. The latter is possible only if $\Pi_1 f = \Pi_2 f$.

Finally, we consider the orthogonality relation. For every real number a and $l \in L$, we have

$$\|f - (\Pi f + al)\|^2 = \|f - \Pi f\|^2 - 2a \operatorname{Re}\langle f - \Pi f, l \rangle + a^2 \|l\|^2.$$

By definition of Πf this is minimal as a function of a at the value $a = 0$, whence the given parabola (in a) must have its bottom at zero, which is the case if and only if $\operatorname{Re}\langle f - \Pi f, l \rangle = 0$. In the complex case we see by a similar argument with ia instead of a , that $\operatorname{Im}\langle f - \Pi f, l \rangle = 0$ as well. Thus $f - \Pi f \perp L$.

Conversely, if $\langle f - \Pi f, l \rangle = 0$ for every $l \in L$ and $\Pi f \in L$, then $\Pi f - l \in L$ for every $l \in L$ and by Pythagoras' rule

$$\|f - l\|^2 = \|(f - \Pi f) + (\Pi f - l)\|^2 = \|f - \Pi f\|^2 + \|\Pi f - l\|^2 \geq \|f - \Pi f\|^2.$$

This proves that Πf minimizes $l \mapsto \|f - l\|^2$ over $l \in L$. ■

The function Πf given in the preceding theorem is called the (orthogonal) *projection* of f onto L . A geometric representation of a projection in \mathbb{R}^3 is given in Figure 2.1.

From the orthogonality characterization of Πf , we can see that the map $f \mapsto \Pi f$ is linear and decreases norm:

$$\begin{aligned} \Pi(f + g) &= \Pi f + \Pi g, \\ \Pi(\alpha f) &= \alpha \Pi f, \\ \|\Pi f\| &\leq \|f\|. \end{aligned}$$

Together linearity and decreasing norm show that Π is Lipschitz continuous: $\|\Pi f - \Pi g\| \leq \|f - g\|$.

A further important property relates to repeated projections. If $\Pi_L f$ denotes the projection of f onto L and L_1 and L_2 are two closed linear subspaces, then

$$\Pi_{L_1} \Pi_{L_2} f = \Pi_{L_1} f, \quad \text{iff } L_1 \subset L_2.$$

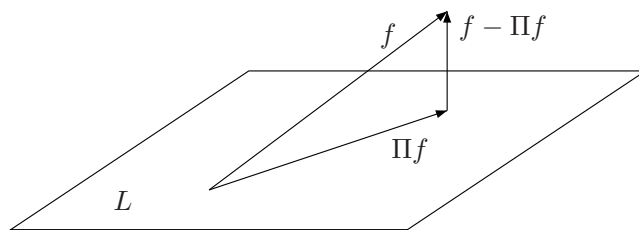

Figure 2.1. Projection of f onto the linear space L . The remainder $f - \Pi f$ is orthogonal to L .

Thus we can find a projection in steps, by projecting a projection ($\Pi_{L_2} f$) onto a bigger space (L_2) a second time onto the smaller space (L_1). This, again, is best proved using the orthogonality relation.

2.12 EXERCISE. Prove the relations in the two preceding displays.

The projection $\Pi_{L_1+L_2}$ onto the sum $L_1 + L_2 = \{l_1 + l_2 : l_i \in L_i\}$ of two closed linear spaces is not necessarily the sum $\Pi_{L_1} + \Pi_{L_2}$ of the projections. (It is also not true that the sum of two closed linear subspaces is necessarily closed, so that $\Pi_{L_1+L_2}$ may not even be well defined.) However, this is true if the spaces L_1 and L_2 are orthogonal:

$$\Pi_{L_1+L_2} f = \Pi_{L_1} f + \Pi_{L_2} f, \quad \text{if } L_1 \perp L_2.$$

2.13 EXERCISE.

- (i) Show by counterexample that the condition $L_1 \perp L_2$ cannot be omitted.
- (ii) Show that $L_1 + L_2$ is closed if $L_1 \perp L_2$ and both L_1 and L_2 are closed subspaces.
- (iii) Show that $L_1 \perp L_2$ implies that $\Pi_{L_1+L_2} = \Pi_{L_1} + \Pi_{L_2}$.

[Hint for (ii): It must be shown that if $z_n = x_n + y_n$ with $x_n \in L_1$, $y_n \in L_2$ for every n and $z_n \rightarrow z$, then $z = x + y$ for some $x \in L_1$ and $y \in L_2$. How can you find x_n and y_n from z_n ? Also remember that a projection is continuous.]

2.14 EXERCISE. Find the projection $\Pi_L f$ of an element f onto a one-dimensional space $L = \{\lambda l_0 : \lambda \in \mathbb{C}\}$.

- * **2.15 EXERCISE.** Suppose that the set L has the form $L = L_1 + iL_2$ for two closed, linear spaces L_1, L_2 of real functions. Show that the minimizer of $l \mapsto \|f - l\|$ over $l \in L$ for a real function f is the same as the minimizer of $l \mapsto \|f - l\|$ over L_1 . Does this imply that $f - \Pi f \perp L_2$? Why does this not follow from the projection theorem?

2.2 Square-integrable Random Variables

For (Ω, \mathcal{U}, P) a probability space the Hilbert space $\mathcal{L}_2(\Omega, \mathcal{U}, P)$ is exactly the set of all complex (or real) random variables X with finite second moment $E|X|^2$. The inner product is the product expectation $\langle X, Y \rangle = EX\bar{Y}$, and the inner product between centered variables is the covariance:

$$\langle X - EX, Y - EY \rangle = \text{cov}(X, Y).$$

The Cauchy-Schwarz inequality takes the form

$$|EX\bar{Y}|^2 \leq E|X|^2 E|Y|^2.$$

When combined the preceding displays imply that $|\text{cov}(X, Y)|^2 \leq \text{var } X \text{ var } Y$. Convergence $X_n \rightarrow X$ relative to the norm means that $E|X_n - X|^2 \rightarrow 0$, and is referred to as *convergence in second mean*. This implies the *convergence in mean* $E|X_n - X| \rightarrow 0$, because $E|X| \leq \sqrt{E|X|^2}$ by the Cauchy-Schwarz inequality. The continuity of the inner product (2.3) gives that:

$$E|X_n - X|^2 \rightarrow 0, E|Y_n - Y|^2 \rightarrow 0 \quad \text{implies} \quad \text{cov}(X_n, Y_n) \rightarrow \text{cov}(X, Y).$$

2.16 EXERCISE. How can you apply this rule to prove equalities of the type $\text{cov}(\sum \alpha_j X_{t-j}, \sum \beta_j Y_{t-j}) = \sum_i \sum_j \alpha_i \bar{\beta}_j \text{cov}(X_{t-i}, Y_{t-j})$, such as in Lemma 1.29?

2.17 EXERCISE. Show that $\text{sd}(X+Y) \leq \text{sd}(X) + \text{sd}(Y)$ for any pair of random variables X and Y .

2.2.1 Conditional Expectation

Let $\mathcal{U}_0 \subset \mathcal{U}$ be a sub σ -field of the σ -field \mathcal{U} . The collection L of all \mathcal{U}_0 -measurable variables $Y \in L_2(\Omega, \mathcal{U}, P)$ is a closed, linear subspace of $L_2(\Omega, \mathcal{U}, P)$. (It can be identified with $L_2(\Omega, \mathcal{U}_0, P)$). By the projection theorem every square-integrable random variable X possesses a projection onto L . This particular projection is important enough to give it a name and study it in more detail.

2.18 Definition. The projection of $X \in L_2(\Omega, \mathcal{U}, P)$ onto the the set of all \mathcal{U}_0 -measurable square-integrable random variables is called the *conditional expectation of X given \mathcal{U}_0* . It is denoted by $E(X|\mathcal{U}_0)$.

Many times the σ -field \mathcal{U}_0 will be generated by a measurable map $Y: \Omega \rightarrow \mathbb{D}$ with values in some measurable space $(\mathbb{D}, \mathcal{D})$: then \mathcal{U}_0 gives the information contained in observing Y . Formally the σ -field generated by Y is defined as $\sigma(Y) = Y^{-1}(\mathcal{D})$, the collection of all events of the form $\{Y \in D\}$, for $D \in \mathcal{D}$. The notation $E(X|Y)$ is an abbreviation of $E(X|\sigma(Y))$, and called the *conditional expectation of X given Y* .

The name “conditional expectation” suggests that there exists another, more intuitive interpretation of this projection. An alternative definition of a conditional expectation is as follows.

2.19 Definition. The conditional expectation given \mathcal{U}_0 of a random variable X which is either nonnegative or integrable is defined as a \mathcal{U}_0 -measurable variable X' such that $EX1_A = EX'1_A$ for every $A \in \mathcal{U}_0$.

It is clear from the definition that any other \mathcal{U}_0 -measurable map X'' such that $X'' = X'$ almost surely is also a conditional expectation. Apart from this indeterminacy on null sets, a conditional expectation as in the second definition can be shown to be unique; its existence can be proved using the Radon-Nikodym theorem. We do not give proofs of these facts here.

Because a variable $X \in L_2(\Omega, \mathcal{U}, P)$ is automatically integrable, Definition 2.19 defines a conditional expectation for a larger class of variables than Definition 2.18. If $E|X|^2 < \infty$, so that both definitions apply, then the two definitions agree. To see this it suffices to show that a projection $E(X|\mathcal{U}_0)$ as in the first definition is the conditional expectation X' of the second definition. Now $E(X|\mathcal{U}_0)$ is \mathcal{U}_0 -measurable by definition and satisfies the equality $E(X - E(X|\mathcal{U}_0))1_A = 0$ for every $A \in \mathcal{U}_0$, by the orthogonality relationship of a projection. Thus $X' = E(X|\mathcal{U}_0)$ satisfies the requirements of Definition 2.19.

The required measurability in the smaller σ -field \mathcal{U}_0 says that the conditional expectation $X' = E(X|\mathcal{U}_0)$ is a “coarsening” of the original variable X : it is based on less information. Definition 2.19 shows that the two variables have the same average values $EX1_A/P(A)$ and $EX'1_A/P(A)$ over every measurable set $A \in \mathcal{U}_0$. Some examples help to gain more insight in conditional expectations.

2.20 Example (Ordinary expectation). The expectation EX of a random variable X is a number, and can be considered a degenerate random variable. It is also the conditional expectation relative to the trivial σ -field: $E(X|\{\emptyset, \Omega\}) = EX$. More generally, we have that $E(X|\mathcal{U}_0) = EX$ if X and \mathcal{U}_0 are independent. This is intuitively clear: “an independent σ -field \mathcal{U}_0 gives no information about X ” and hence the expectation given \mathcal{U}_0 is the unconditional expectation.

To derive this from the definition, note that $E(EX)1_A = EXE1_A = EX1_A$ for every measurable set A such that X and A are independent. \square

2.21 Example (Full information). At the other extreme we have that $E(X|\mathcal{U}_0) = X$ if X itself is \mathcal{U}_0 -measurable. This is immediate from the definition. “Given \mathcal{U}_0 we know X exactly.” \square

2.22 EXERCISE. Let $\mathcal{U}_0 = \sigma(A_1, \dots, A_k)$ for a measurable partition $\Omega = \cup_i A_i$ into finitely many sets of positive probability. Show that the random variable $E(X|\mathcal{U}_0)$ takes the value $EX1_{A_i}/P(A_i)$ on the event A_i .

2.23 Example (Conditional density). Let $(X, Y): \Omega \rightarrow \mathbb{R} \times \mathbb{R}^k$ be measurable and possess a density $f(x, y)$ relative to a σ -finite product measure $\mu \times \nu$ on $\mathbb{R} \times \mathbb{R}^k$ (for instance, the Lebesgue measure on \mathbb{R}^{k+1}). Then it is customary to define a *conditional density* of X given $Y = y$ by

$$f(x|y) = \frac{f(x, y)}{\int f(x, y) d\mu(x)}.$$

This is well defined for every y for which the denominator is positive. As the denominator is precisely the marginal density f_Y of Y evaluated at y , this is for all y in a set of measure one under the distribution of Y .

We now have that the conditional expectation is given by the “usual formula”

$$E(X|Y) = \int x f(x|Y) d\mu(x).$$

Here we may define the right hand arbitrarily if the denominator of $f(x|Y)$ is zero.

That this formula is the conditional expectation according to Definition 2.19 follows by some applications of Fubini’s theorem. To begin with, note that it is a part of the statement of this theorem that the right side of the preceding display is a measurable function of Y . Next we write $EE(X|Y)1_{Y \in B}$, for an arbitrary measurable set B , in the form $\int_B \int x f(x|y) d\mu(x) f_Y(y) d\nu(y)$. Because $f(x|y)f_Y(y) = f(x, y)$ for almost every (x, y) , the latter expression is equal to $EX1_{Y \in B}$, by Fubini’s theorem. \square

2.24 Lemma (Properties).

- (i) $EE(X|\mathcal{U}_0) = EX$.
- (ii) If Z is \mathcal{U}_0 -measurable, then $E(ZX|\mathcal{U}_0) = ZE(X|\mathcal{U}_0)$ a.s.. (Here require that $X \in L_p(\Omega, \mathcal{U}, P)$ and $Z \in L_q(\Omega, \mathcal{U}, P)$ for $1 \leq p \leq \infty$ and $p^{-1} + q^{-1} = 1$.)
- (iii) (linearity) $E(\alpha X + \beta Y|\mathcal{U}_0) = \alpha E(X|\mathcal{U}_0) + \beta E(Y|\mathcal{U}_0)$ a.s..
- (iv) (positivity) If $X \geq 0$ a.s., then $E(X|\mathcal{U}_0) \geq 0$ a.s..
- (v) (towering property) If $\mathcal{U}_0 \subset \mathcal{U}_1 \subset \mathcal{U}$, then $E(E(X|\mathcal{U}_1)|\mathcal{U}_0) = E(X|\mathcal{U}_0)$ a.s..

The conditional expectation $E(X|Y)$ given a random vector Y is by definition a $\sigma(Y)$ -measurable function. The following lemma shows that, for most Y , this means that it is a measurable function $g(Y)$ of Y . The value $g(y)$ is often denoted by $E(X|Y = y)$.

Warning. Unless $P(Y = y) > 0$ it is not right to give a meaning to $E(X|Y = y)$ for a fixed, single y , even though the interpretation as an expectation given “that we know that $Y = y$ ” often makes this tempting (and often leads to a correct result). We may only think of a conditional expectation as a function $y \mapsto E(X|Y = y)$ and this is only determined up to null sets.

2.25 Lemma. Let $\{Y_\alpha: \alpha \in A\}$ be random variables on Ω and let X be a $\sigma(Y_\alpha: \alpha \in A)$ -measurable random variable.

- (i) If $A = \{1, 2, \dots, k\}$, then there exists a measurable map $g: \mathbb{R}^k \rightarrow \mathbb{R}$ such that $X = g(Y_1, \dots, Y_k)$.
- (ii) If $|A| = \infty$, then there exists a countable subset $\{\alpha_n\}_{n=1}^\infty \subset A$ and a measurable map $g: \mathbb{R}^\infty \rightarrow \mathbb{R}$ such that $X = g(Y_{\alpha_1}, Y_{\alpha_2}, \dots)$.

Proof. For the proof of (i), see e.g. Dudley Theorem 4.28. \blacksquare

2.3 Linear Prediction

Suppose that we observe the values X_1, \dots, X_n from a stationary, mean zero time series X_t . The *linear prediction problem* is to find the linear combination of these variables that best predicts future variables.

2.26 Definition. *Given a mean zero time series X_t , the best linear predictor of X_{n+1} is the linear combination $\phi_1 X_n + \phi_2 X_{n-1} + \dots + \phi_n X_1$ that minimizes $E|X_{n+1} - Y|^2$ over all linear combinations Y of X_1, \dots, X_n . The minimal value $E|X_{n+1} - \phi_1 X_n - \dots - \phi_n X_1|^2$ is called the square prediction error.*

In the terminology of the preceding section, the best linear predictor of X_{n+1} is the projection of X_{n+1} onto the linear subspace $\text{lin}(X_1, \dots, X_n)$ spanned by X_1, \dots, X_n . A common notation is $\Pi_n X_{n+1}$, for Π_n the projection onto $\text{lin}(X_1, \dots, X_n)$. Best linear predictors of other random variables are defined similarly.

Warning. The coefficients ϕ_1, \dots, ϕ_n in the formula $\Pi_n X_{n+1} = \phi_1 X_n + \dots + \phi_n X_1$ depend on n , even though we often suppress this dependence in the notation. The reversed ordering of the labels on the coefficients ϕ_i is for convenience.

By Theorem 2.11 the best linear predictor can be found from the *prediction equations*

$$\langle X_{n+1} - \phi_1 X_n - \dots - \phi_n X_1, X_t \rangle = 0, \quad t = 1, \dots, n,$$

where $\langle \cdot, \cdot \rangle$ is the inner product in $L_2(\Omega, \mathcal{U}, P)$. For a stationary (real-valued!) time series X_t this system can be written in the form

$$(2.4) \quad \begin{pmatrix} \gamma_X(0) & \gamma_X(1) & \cdots & \gamma_X(n-1) \\ \gamma_X(1) & \gamma_X(0) & \cdots & \gamma_X(n-2) \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_X(n-1) & \gamma_X(n-2) & \cdots & \gamma_X(0) \end{pmatrix} \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_n \end{pmatrix} = \begin{pmatrix} \gamma_X(1) \\ \vdots \\ \gamma_X(n) \end{pmatrix}.$$

If the $(n \times n)$ -matrix on the left is nonsingular, then ϕ_1, \dots, ϕ_n can be solved uniquely. Otherwise there are multiple solutions for the vector (ϕ_1, \dots, ϕ_n) , but any solution will give the best linear predictor $\Pi_n X_{n+1} = \phi_1 X_n + \dots + \phi_n X_1$, as this is uniquely determined by the projection theorem. The equations express ϕ_1, \dots, ϕ_n in the auto-covariance function γ_X . In practice, we do not know this function, but estimate it from the data, and use the corresponding estimates for ϕ_1, \dots, ϕ_n to calculate the predictor. (We consider the estimation problem in later chapters.)

The square prediction error can be expressed in the coefficients by Pythagoras' rule, which gives, for a stationary time series X_t ,

$$(2.5) \quad \begin{aligned} E|X_{n+1} - \Pi_n X_{n+1}|^2 &= E|X_{n+1}|^2 - E|\Pi_n X_{n+1}|^2 \\ &= \gamma_X(0) - (\phi_1, \dots, \phi_n) \Gamma_n (\phi_1, \dots, \phi_n)^T, \end{aligned}$$

for Γ_n the covariance matrix of the vector (X_1, \dots, X_n) , i.e. the matrix on the left side of (2.4).

Similar arguments apply to predicting X_{n+h} for $h > 1$. If we wish to predict the future values at many time lags $h = 1, 2, \dots$, then solving a n -dimensional linear system for

every h separately can be computer-intensive, as n may be large. Several more efficient, recursive algorithms use the predictions at earlier times to calculate the next prediction, and are computationally more efficient. We discuss one of these in Section 2.4.

2.27 Example (Autoregression). Prediction is extremely simple for the stationary auto-regressive time series satisfying $X_t = \phi X_{t-1} + Z_t$ for a white noise sequence Z_t and $|\phi| < 1$: the best linear predictor of X_{n+1} given X_1, \dots, X_n is simply ϕX_n (for $n \geq 1$). Thus we predict $X_{n+1} = \phi X_n + Z_{n+1}$ by simply setting the unknown Z_{n+1} equal to its mean, zero. The interpretation is that the Z_t are external noise factors that are completely unpredictable based on the past. The square prediction error $E|X_{n+1} - \phi X_n|^2 = EZ_{n+1}^2$ is equal to the variance of this “innovation”.

The claim is not obvious, as is proved by the fact that it is wrong in the case that $|\phi| > 1$. To prove the claim we recall from Example 1.8 that the unique stationary solution to the auto-regressive equation in the case that $|\phi| < 1$ is given by $X_t = \sum_{j=0}^{\infty} \phi^j Z_{t-j}$. Thus X_t depends only on Z_s from the past and the present. Because Z_t is a white noise sequence, it follows that Z_{t+1} is uncorrelated with the variables X_t, X_{t-1}, \dots . Therefore $\langle X_{n+1} - \phi X_n, X_t \rangle = \langle Z_{n+1}, X_t \rangle = 0$ for $t = 1, 2, \dots, n$. This verifies the orthogonality relationship; it is obvious that ϕX_n is contained in the linear span of X_1, \dots, X_n . \square

2.28 EXERCISE. There is a hidden use of the continuity of the inner product in the preceding example. Can you see where?

* **2.29 EXERCISE.** Find the best linear predictor of X_{n+1} given X_n, X_{n-1}, \dots , and given X_n, \dots, X_1 in the stationary autoregressive process satisfying $X_t = \phi X_{t-1} + Z_t$ for a white noise sequence Z_t and $|\phi| > 1$.

2.30 Example (Deterministic trigonometric series). For the process $X_t = A \cos(\lambda t) + B \sin(\lambda t)$, considered in Example 1.5, the best linear predictor of X_{n+1} given X_1, \dots, X_n is given by $2(\cos \lambda)X_n - X_{n-1}$, for $n \geq 2$. The prediction error is equal to 0! This underscores that this type of time series is deterministic in character: if we know it at two time instants, then we know the time series at all other time instants. The intuitive explanation is that the values A and B can be recovered from the values of X_t at two time instants.

These assertions follow by explicit calculations, solving the prediction equations. It suffices to do this for $n = 2$: if X_3 can be predicted without error by $2(\cos \lambda)X_2 - X_1$, then, by stationarity, X_{n+1} can be predicted without error by $2(\cos \lambda)X_n - X_{n-1}$. \square

2.31 EXERCISE.

- (i) Prove the assertions in the preceding example.
- (ii) Are the coefficients $2 \cos \lambda, -1, 0, \dots, 0$ in this example unique?

If a given time series X_t is not centered at 0, then it is natural to allow a constant term in the predictor. Write 1 for the random variable that is equal to 1 almost surely.

2.32 Definition. *The best linear predictor of X_{n+1} based on X_1, \dots, X_n is the projection of X_{n+1} onto the linear space spanned by $1, X_1, \dots, X_n$.*

If the time series X_t does have mean zero, then the introduction of the constant term 1 does not help. Indeed, the relation $EX_t = 0$ is equivalent to $X_t \perp 1$, which implies both that $1 \perp \text{lin}(X_1, \dots, X_n)$ and that the projection of X_{n+1} onto $\text{lin } 1$ is zero. By the orthogonality the projection of X_{n+1} onto $\text{lin}(1, X_1, \dots, X_n)$ is the sum of its projections onto $\text{lin } 1$ and $\text{lin}(X_1, \dots, X_n)$. As the first projection is 0, this is the projection onto $\text{lin}(X_1, \dots, X_n)$.

If the mean of the time series is nonzero, then adding a constant to the predictor does cut the prediction error. By a similar argument as in the preceding paragraph we see that for a time series with mean $\mu = EX_t$ possibly nonzero,

$$(2.6) \quad \Pi_{\text{lin}(1, X_1, \dots, X_n)} X_{n+1} = \mu + \Pi_{\text{lin}(X_1 - \mu, \dots, X_n - \mu)} (X_{n+1} - \mu).$$

Thus the recipe for prediction with uncentered time series is: subtract the mean from every X_t , calculate the projection for the centered time series $X_t - \mu$, and finally add the mean. Because the auto-covariance function γ_X gives the inner products of the centered process, the coefficients ϕ_1, \dots, ϕ_n of $X_n - \mu, \dots, X_1 - \mu$ are still given by the prediction equations (2.4).

2.33 EXERCISE. Prove formula (2.6), noting that $EX_t = \mu$ is equivalent to $X_t - \mu \perp 1$.

* 2.4 Innovations Algorithm

The prediction error $X_n - \Pi_{n-1}X_n$ at time n is called the *innovation* at time n . (Set $\Pi_0 X_1 = EX_1$, so that at time 1 we predict using constants.) The linear span of the innovations $X_1 - \Pi_0 X_1, \dots, X_n - \Pi_{n-1}X_n$ is the same as the linear span X_1, \dots, X_n , and hence the linear predictor of X_{n+1} can be expressed in the innovations, as

$$\Pi_n X_{n+1} = \psi_{n,1}(X_n - \Pi_{n-1}X_n) + \psi_{n,2}(X_{n-1} - \Pi_{n-2}X_{n-1}) + \dots + \psi_{n,n}(X_1 - \Pi_0 X_1).$$

The *innovations algorithm* shows how the triangular array of coefficients $\psi_{n,1}, \dots, \psi_{n,n}$ can be efficiently computed. Once these coefficients are known, predictions further into the future can also be computed easily. Indeed by the towering property of projections the projection $\Pi_k X_{n+1}$ for $k \leq n$ can be obtained by applying Π_k to the left side of the preceding display. Next the linearity of projection and the orthogonality of the innovations to the “past” yields that, for $k \leq n$,

$$\Pi_k X_{n+1} = \psi_{n,n-k+1}(X_k - \Pi_{k-1}X_k) + \dots + \psi_{n,n}(X_1 - \Pi_0 X_1).$$

We just drop the innovations that are future to time k .

The innovations algorithm computes the coefficients $\psi_{n,t}$ for $n = 1, 2, \dots$, and for every n backwards for $t = n, n-1, \dots, 1$. It also uses and computes the square norms of the innovations

$$v_{n-1} := E(X_n - \Pi_{n-1}X_n)^2.$$

The algorithm is initialized at $n = 1$ by setting $\Pi_0X_1 = EX_1$ and $v_0 = \text{var } X_1 = \gamma_X(0)$. For each n the last of the coefficients $\psi_{n,t}$ is computed as (cf. Exercise 2.14)

$$\psi_{n,n} = \frac{\text{cov}(X_{n+1}, X_1)}{\text{var } X_1} = \frac{\gamma_X(n)}{v_0}.$$

In particular, this yields the single coefficient $\psi_{1,1}$ at level $n = 1$. Once all coefficients at level n and v_0, \dots, v_{n-1} are known, we compute

$$v_n = \text{var } X_{n+1} - \text{var } \Pi_n X_{n+1} = \gamma_X(0) - \sum_{t=1}^n \psi_{n,t}^2 v_{n-t}.$$

Next if the coefficients $(\psi_{j,t})$ are known for $j = 1, \dots, n-1$, then for $t = n-1, \dots, 1$,

$$\begin{aligned} \psi_{n,t} &= \frac{\text{cov}(X_{n+1}, X_{n+1-t} - \Pi_{n-t}X_{n+1-t})}{\text{var}(X_{n+1-t} - \Pi_{n-t}X_{n+1-t})} \\ &= \frac{\gamma_X(t) - \psi_{n-t,1}\psi_{n,t+1}v_{n-t-1} - \psi_{n-t,2}\psi_{n,t+2}v_{n-t-2} - \dots - \psi_{n-t,n-t}\psi_{n,n}v_0}{v_{n-t}}. \end{aligned}$$

In the last step we have replaced $\Pi_{n-t}X_{n+1-t}$ by

$$\sum_{j=1}^{n-t} \psi_{n-t,j}(X_{n+1-t-j} - \Pi_{n-t-j}X_{n+1-t-j}),$$

and next used that

$$\begin{aligned} &\text{cov}(X_{n+1}, X_{n+1-t-j} - \Pi_{n-t-j}X_{n+1-t-j}) \\ &= \text{cov}(\Pi_n X_{n+1}, X_{n+1-t-j} - \Pi_{n-t-j}X_{n+1-t-j}) = \psi_{n,t+j}v_{n-t-j}. \end{aligned}$$

2.5 Nonlinear Prediction

The method of linear prediction is commonly used in time series analysis. Its main advantage is simplicity: the linear predictor depends on the mean and auto-covariance function only, and in a simple fashion. On the other hand, utilization of general functions $f(X_1, \dots, X_n)$ of the observations as predictors may decrease the prediction error.

2.34 Definition. The best predictor of X_{n+1} based on X_1, \dots, X_n is the function $f_n(X_1, \dots, X_n)$ that minimizes $E|X_{n+1} - f(X_1, \dots, X_n)|^2$ over all measurable functions $f: \mathbb{R}^n \rightarrow \mathbb{R}$.

In view of the discussion in Section 2.2.1 the best predictor is the conditional expectation $E(X_{n+1} | X_1, \dots, X_n)$ of X_{n+1} given the variables X_1, \dots, X_n . Best predictors of other variables are similarly defined as conditional expectations.

The difference between linear and nonlinear predictors can be substantial. In “classical” time series theory linear models with Gaussian errors were predominant and for those models the two predictors coincide. However, for nonlinear models, or non-Gaussian distributions, nonlinear prediction should be the method of choice, if feasible.

2.35 Example (GARCH). In the GARCH model of Example 1.10 the variable X_{n+1} is given as $\sigma_{n+1}Z_{n+1}$, where σ_{n+1} is a function of X_n, X_{n-1}, \dots and Z_{n+1} is independent of these variables. It follows that the best predictor of X_{n+1} given the infinite past X_n, X_{n-1}, \dots is given by $\sigma_{n+1}E(Z_{n+1} | X_n, X_{n-1}, \dots) = 0$. We can find the best predictor given X_n, \dots, X_1 by projecting this predictor further onto the space of all measurable functions of X_n, \dots, X_1 . By the linearity of the projection we again find 0.

We conclude that a GARCH model does not allow a “true prediction” of the future, if “true” refers to predicting the values of the time series itself.

On the other hand, we can predict other quantities of interest. For instance, the uncertainty of the value of X_{n+1} is determined by the size of the “volatility” σ_{n+1} . If σ_{n+1} is close to zero, then we may expect X_{n+1} to be close to zero, and conversely. Given the infinite past X_n, X_{n-1}, \dots the variable σ_{n+1} is known completely, but in the more realistic situation that we know only X_n, \dots, X_1 some chance component will be left.

For large n the difference between these two situations is small. The dependence of σ_{n+1} on X_n, X_{n-1}, \dots is given in Example 1.10 as $\sigma_{n+1}^2 = \sum_{j=0}^{\infty} \phi^j(\alpha + \theta X_{n-j}^2)$ and is nonlinear. For large n this is close to $\sum_{j=0}^{n-1} \phi^j(\alpha + \theta X_{n-j}^2)$, which is a function of X_1, \dots, X_n . By definition the best predictor $\hat{\sigma}_{n+1}^2$ based on X_1, \dots, X_n is the closest function and hence it satisfies

$$E|\hat{\sigma}_{n+1}^2 - \sigma_{n+1}^2|^2 \leq E\left|\sum_{j=0}^{n-1} \phi^j(\alpha + \theta X_{n-j}^2) - \sigma_{n+1}^2\right|^2 = E\left|\sum_{j=n}^{\infty} \phi^j(\alpha + \theta X_{n-j}^2)\right|^2.$$

For small ϕ and large n this will be small if the sequence X_n is sufficiently integrable. Thus accurate nonlinear prediction of σ_{n+1}^2 is feasible. \square

2.6 Partial Auto-Correlation

For a mean-zero stationary time series X_t the *partial auto-correlation* at lag $h \geq 1$ is defined as the correlation between $X_h - \Pi_{h-1}X_h$ and $X_0 - \Pi_{h-1}X_0$, where Π_h is the

projection onto $\text{lin}(X_1, \dots, X_h)$ (with the convention that this space is the point 0 if $h = 0$). This is the “correlation between X_h and X_0 with the correlation due to the intermediate variables X_1, \dots, X_{h-1} removed”. We shall denote it by

$$\alpha_X(h) = \rho(X_h - \Pi_{h-1}X_h, X_0 - \Pi_{h-1}X_0).$$

For an uncentered stationary time series we set the partial auto-correlation by definition equal to the partial auto-correlation of the centered series $X_t - EX_t$. We also define $\alpha_X(0) = 1$. A convenient method to compute α_X is given by the prediction equations combined with the following lemma, which shows that $\alpha_X(h)$ is the coefficient of X_1 in the best linear predictor of X_{h+1} based on X_1, \dots, X_h .

2.36 Lemma. *Suppose that X_t is a mean-zero stationary time series. If $\phi_1 X_h + \phi_2 X_{h-1} + \dots + \phi_h X_1$ is the best linear predictor of X_{h+1} based on X_1, \dots, X_h , then $\alpha_X(h) = \phi_h$.*

Proof. Let $\psi_1 X_h + \dots + \psi_{h-1} X_2 =: \Pi_{2,h} X_1$ be the best linear predictor of X_1 based on X_2, \dots, X_h . The best linear predictor of X_{h+1} based on X_1, \dots, X_h can be decomposed as

$$\begin{aligned} \Pi_h X_{h+1} &= \phi_1 X_h + \dots + \phi_h X_1 \\ &= [(\phi_1 + \phi_h \psi_1) X_h + \dots + (\phi_{h-1} + \phi_h \psi_{h-1}) X_2] + [\phi_h (X_1 - \Pi_{2,h} X_1)]. \end{aligned}$$

The two random variables in square brackets are orthogonal, because $X_1 - \Pi_{2,h} X_1 \perp \text{lin}(X_2, \dots, X_h)$ by the projection theorem. Therefore, the second variable in square brackets is the projection of $\Pi_h X_{h+1}$ onto the one-dimensional subspace $\text{lin}(X_1 - \Pi_{2,h} X_1)$. It is also the projection of X_{h+1} onto this one-dimensional subspace, because $\text{lin}(X_1 - \Pi_{2,h} X_1) \subset \text{lin}(X_1, \dots, X_h)$ and we can compute projections by first projecting onto a bigger subspace.

The projection of X_{h+1} onto the one-dimensional subspace $\text{lin}(X_1 - \Pi_{2,h} X_1)$ is easily computed directly as $\alpha(X_1 - \Pi_{2,h} X_1)$, for

$$\alpha = \frac{\langle X_{h+1}, X_1 - \Pi_{2,h} X_1 \rangle}{\|X_1 - \Pi_{2,h} X_1\|^2} = \frac{\langle X_{h+1} - \Pi_{2,h} X_{h+1}, X_1 - \Pi_{2,h} X_1 \rangle}{\|X_1 - \Pi_{2,h} X_1\|^2}.$$

As it depends on the auto-covariance function only, the linear prediction problem is symmetric in time, and hence $\|X_1 - \Pi_{2,h} X_1\| = \|X_{h+1} - \Pi_{2,h} X_{h+1}\|$. Therefore, the right side is exactly $\alpha_X(h)$. In view of the preceding paragraph, we have $\alpha = \phi_h$ and the lemma is proved. ■

2.37 Example (Autoregression). According to Example 2.27, for the stationary autoregressive process $X_t = \phi X_{t-1} + Z_t$ with $|\phi| < 1$, the best linear predictor of X_{n+1} based on X_1, \dots, X_n is ϕX_n , for $n \geq 1$. Thus $\alpha_X(1) = \phi$ and the partial auto-correlations $\alpha_X(h)$ of lags $h > 1$ are zero. This is often viewed as the dual of the property that for the moving average sequence of order 1, considered in Example 1.6, the auto-correlations of lags $h > 1$ vanish.

In Chapter 8 we shall see that for higher order stationary autoregressive processes $X_t = \phi_1 X_{t-1} + \dots + \phi_p X_{t-p} + Z_t$ the partial auto-correlations of lags $h > p$ are zero under the (standard) assumption that the time series is “causal”. □

3

Stochastic Convergence

This chapter provides a review of modes of convergence of sequences of stochastic vectors. In particular, convergence in distribution and in probability. Many proofs are omitted, but can be found in most standard probability books, and certainly in the book *Asymptotic Statistics* (A.W. van der Vaart, 1998).

3.1 Basic theory

A *random vector* in \mathbb{R}^k is a vector $X = (X_1, \dots, X_k)$ of real random variables. More formally it is a Borel measurable map from some probability space in \mathbb{R}^k . The *distribution function* of X is the map $x \mapsto P(X \leq x)$.

A sequence of random vectors X_n is said to *converge in distribution* to X if

$$P(X_n \leq x) \rightarrow P(X \leq x),$$

for every x at which the distribution function $x \mapsto P(X \leq x)$ is continuous. Alternative names are *weak convergence* and *convergence in law*. As the last name suggests, the convergence only depends on the induced laws of the vectors and not on the probability spaces on which they are defined. We denote weak convergence by $X_n \rightsquigarrow X$; if X has distribution L or a distribution with a standard code such as $N(0, 1)$, then also by $X_n \rightsquigarrow L$ or $X_n \rightsquigarrow N(0, 1)$.

Let $d(x, y)$ be any distance function on \mathbb{R}^k that generates the usual topology. For instance

$$d(x, y) = \|x - y\| = \left(\sum_{i=1}^k (x_i - y_i)^2 \right)^{1/2}.$$

A sequence of random variables X_n is said to *converge in probability* to X if for all $\varepsilon > 0$

$$P(d(X_n, X) > \varepsilon) \rightarrow 0.$$

This is denoted by $X_n \xrightarrow{P} X$. In this notation convergence in probability is the same as $d(X_n, X) \xrightarrow{P} 0$.

As we shall see convergence in probability is stronger than convergence in distribution. Even stronger modes of convergence are almost sure convergence and convergence in p th mean. The sequence X_n is said to *converge almost surely* to X if $d(X_n, X) \rightarrow 0$ with probability one:

$$P(\lim d(X_n, X) = 0) = 1.$$

This is denoted by $X_n \xrightarrow{as} X$. The sequence X_n is said to *converge in p th mean* to X if

$$Ed(X_n, X)^p \rightarrow 0.$$

This is denoted $X_n \xrightarrow{L_p} X$. We already encountered the special cases $p = 1$ or $p = 2$, which are referred to as “convergence in mean” and “convergence in quadratic mean”.

Convergence in probability, almost surely, or in mean only make sense if each X_n and X are defined on the same probability space. For convergence in distribution this is not necessary.

The portmanteau lemma gives a number of equivalent descriptions of weak convergence. Most of the characterizations are only useful in proofs. The last one also has intuitive value.

3.1 Lemma (Portmanteau). *For any random vectors X_n and X the following statements are equivalent.*

- (i) $P(X_n \leq x) \rightarrow P(X \leq x)$ for all continuity points of $x \rightarrow P(X \leq x)$;
- (ii) $Ef(X_n) \rightarrow Ef(X)$ for all bounded, continuous functions f ;
- (iii) $Ef(X_n) \rightarrow Ef(X)$ for all bounded, Lipschitz[†] functions f ;
- (iv) $\liminf P(X_n \in G) \geq P(X \in G)$ for every open set G ;
- (v) $\limsup P(X_n \in F) \leq P(X \in F)$ for every closed set F ;
- (vi) $P(X_n \in B) \rightarrow P(X \in B)$ for all Borel sets B with $P(X \in \delta B) = 0$ where $\delta B = \overline{B} - \overset{\circ}{B}$ is the boundary of B .

The continuous mapping theorem is a simple result, but is extremely useful. If the sequence of random vector X_n converges to X and g is continuous, then $g(X_n)$ converges to $g(X)$. This is true without further conditions for three of our four modes of stochastic convergence.

3.2 Theorem (Continuous mapping). *Let $g: \mathbb{R}^k \rightarrow \mathbb{R}^m$ be measurable and continuous at every point of a set C such that $P(X \in C) = 1$.*

- (i) *If $X_n \rightsquigarrow X$, then $g(X_n) \rightsquigarrow g(X)$;*
- (ii) *If $X_n \xrightarrow{P} X$, then $g(X_n) \xrightarrow{P} g(X)$;*
- (iii) *If $X_n \xrightarrow{as} X$, then $g(X_n) \xrightarrow{as} g(X)$.*

Any random vector X is *tight*: for every $\varepsilon > 0$ there exists a constant M such that $P(\|X\| > M) < \varepsilon$. A set of random vectors $\{X_\alpha: \alpha \in A\}$ is called *uniformly tight* if M

[†] A function is called *Lipschitz* if there exists a number L such that $|f(x) - f(y)| \leq Ld(x, y)$ for every x and y . The least such number L is denoted $\|f\|_{Lip}$.

can be chosen the same for every X_α : for every $\varepsilon > 0$ there exists a constant M such that

$$\sup_{\alpha} P(\|X_\alpha\| > M) < \varepsilon.$$

Thus there exists a compact set to which all X_α give probability almost one. Another name for uniformly tight is *bounded in probability*. It is not hard to see that every weakly converging sequence X_n is uniformly tight. More surprisingly, the converse of this statement is almost true: according to Prohorov's theorem every uniformly tight sequence contains a weakly converging subsequence.

3.3 Theorem (Prohorov's theorem). *Let X_n be random vectors in \mathbb{R}^k .*

- (i) *If $X_n \rightsquigarrow X$ for some X , then $\{X_n: n \in \mathbb{N}\}$ is uniformly tight;*
- (ii) *If X_n is uniformly tight, then there is a subsequence with $X_{n_j} \rightsquigarrow X$ as $j \rightarrow \infty$ for some X .*

3.4 Example. A sequence X_n of random variables with $E|X_n| = O(1)$ is uniformly tight. This follows since by Markov's inequality: $P(|X_n| > M) \leq E|X_n|/M$. This can be made arbitrarily small uniformly in n by choosing sufficiently large M .

The first absolute moment could of course be replaced by any other absolute moment. Since the second moment is the sum of the variance and the square of the mean an alternative sufficient condition for uniform tightness is: $EX_n = O(1)$ and $\text{var } X_n = O(1)$. \square

Consider some of the relationships between the three modes of convergence. Convergence in distribution is weaker than convergence in probability, which is in turn weaker than almost sure convergence and convergence in p th mean.

3.5 Theorem. *Let X_n , X and Y_n be random vectors. Then*

- (i) $X_n \xrightarrow{\text{as}} X$ implies $X_n \xrightarrow{P} X$;
- (ii) $X_n \xrightarrow{L_2} X$ implies $X_n \xrightarrow{P} X$;
- (iii) $X_n \xrightarrow{P} X$ implies $X_n \rightsquigarrow X$;
- (iv) $X_n \xrightarrow{P} c$ for a constant c if and only if $X_n \rightsquigarrow c$;
- (v) if $X_n \rightsquigarrow X$ and $d(X_n, Y_n) \xrightarrow{P} 0$, then $Y_n \rightsquigarrow X$;
- (vi) if $X_n \rightsquigarrow X$ and $Y_n \xrightarrow{P} c$ for a constant c , then $(X_n, Y_n) \rightsquigarrow (X, c)$;
- (vii) if $X_n \xrightarrow{P} X$ and $Y_n \xrightarrow{P} Y$, then $(X_n, Y_n) \xrightarrow{P} (X, Y)$.

According to the last assertion of the lemma convergence in probability of a sequence of vectors $X_n = (X_{n,1}, \dots, X_{n,k})$ is equivalent to convergence of every one of the sequences of components $X_{n,i}$ separately. The analogous statement for convergence in distribution is false: convergence in distribution of the sequence X_n is stronger than convergence of every one of the sequences of components $X_{n,i}$. The point is that the distribution of the components $X_{n,i}$ separately does not determine their joint distribution: they might be independent or dependent in many ways. One speaks of *joint convergence* in distribution versus *marginal convergence*.

The one before last assertion of the lemma has some useful consequences. If $X_n \rightsquigarrow X$ and $Y_n \rightsquigarrow c$, then $(X_n, Y_n) \rightsquigarrow (X, c)$. Consequently, by the continuous mapping theorem $g(X_n, Y_n) \rightsquigarrow g(X, c)$ for every map g that is continuous at the set $\mathbb{R}^k \times \{c\}$ where the vector (X, c) takes its values. Thus for every g such that

$$\lim_{x \rightarrow x_0, y \rightarrow c} g(x, y) = g(x_0, c), \quad \text{every } x_0.$$

Some particular applications of this principle are known as Slutsky's lemma.

3.6 Lemma (Slutsky). *Let X_n , X and Y_n be random vectors or variables. If $X_n \rightsquigarrow X$ and $Y_n \rightsquigarrow c$ for a constant c , then*

- (i) $X_n + Y_n \rightsquigarrow X + c$;
- (ii) $Y_n X_n \rightsquigarrow cX$;
- (iii) $X_n/Y_n \rightsquigarrow X/c$ provided $c \neq 0$.

In (i) the “constant” c must be a vector of the same dimension as X , and in (ii) c is probably initially understood to be a scalar. However, (ii) is also true if every Y_n and c are matrices (which can be identified with vectors, for instance by aligning rows, to give a meaning to the convergence $Y_n \rightsquigarrow c$), simply because matrix multiplication $(y, x) \rightarrow yx$ is a continuous operation. Another true result in this case is that $X_n Y_n \rightsquigarrow Xc$, if this statement is well defined. Even (iii) is valid for matrices Y_n and c and vectors X_n provided $c \neq 0$ is understood as c being invertible and division is interpreted as (pre)multiplication by the inverse, because taking an inverse is also continuous.

3.7 Example. Let T_n and S_n be statistical estimators satisfying

$$\sqrt{n}(T_n - \theta) \rightsquigarrow N(0, \sigma^2), \quad S_n^2 \xrightarrow{P} \sigma^2,$$

for certain parameters θ and σ^2 depending on the underlying distribution, for every distribution in the model. Then $\theta = T_n \pm S_n/\sqrt{n} \xi_\alpha$ is a confidence interval for θ of asymptotic level $1 - 2\alpha$.

This is a consequence of the fact that the sequence $\sqrt{n}(T_n - \theta)/S_n$ is asymptotically standard normal distributed. \square

* 3.2 Convergence of Moments

By the portmanteau lemma, weak convergence $X_n \rightsquigarrow X$ implies that $Ef(X_n) \rightarrow Ef(X)$ for every continuous, bounded function f . The condition that f be bounded is not superfluous: it is not difficult to find examples of a sequence $X_n \rightsquigarrow X$ and an unbounded, continuous function f for which the convergence fails. In particular, in general convergence in distribution does not imply convergence $EX_n^p \rightarrow EX^p$ of moments. However, in many situations such convergence occurs, but it requires more effort to prove it.

A sequence of random variables Y_n is called *asymptotically uniformly integrable* if

$$\lim_{M \rightarrow \infty} \limsup_{n \rightarrow \infty} E|Y_n| 1\{|Y_n| > M\} = 0.$$

A simple sufficient condition for this is that for some $p > 1$ the sequence $E|Y_n|^p$ is bounded in n .

Uniform integrability is the missing link between convergence in distribution and convergence of moments.

3.8 Theorem. *Let $f: \mathbb{R}^k \rightarrow \mathbb{R}$ be measurable and continuous at every point in a set C . Let $X_n \rightsquigarrow X$ where X takes its values in C . Then $Ef(X_n) \rightarrow Ef(X)$ if and only if the sequence of random variables $f(X_n)$ is asymptotically uniformly integrable.*

3.9 Example. Suppose X_n is a sequence of random variables such that $X_n \rightsquigarrow X$ and $\limsup E|X_n|^p < \infty$ for some p . Then all moments of order strictly less than p converge also: $EX_n^k \rightarrow EX^k$ for every $k < p$.

By the preceding theorem, it suffices to prove that the sequence X_n^k is asymptotically uniformly integrable. By Markov's inequality

$$E|X_n|^k 1\{|X_n|^k \geq M\} \leq M^{1-p/k} E|X_n|^p.$$

The limsup, as $n \rightarrow \infty$ followed by $M \rightarrow \infty$, of the right side is zero if $k < p$. \square

3.3 Arrays

Consider an infinite array $x_{n,l}$ of numbers, indexed by $(n, l) \in \mathbb{N} \times \mathbb{N}$, such that every column has a limit, and the limits x_l themselves converge to a limit along the columns.

$$\begin{array}{cccccc} x_{1,1} & x_{1,2} & x_{1,3} & x_{1,4} & \dots & \\ x_{2,1} & x_{2,2} & x_{2,3} & x_{2,4} & \dots & \\ x_{3,1} & x_{3,2} & x_{3,3} & x_{3,4} & \dots & \\ \vdots & \vdots & \vdots & \vdots & \dots & \\ \downarrow & \downarrow & \downarrow & \downarrow & \dots & \\ x_1 & x_2 & x_3 & x_4 & \dots & \rightarrow x \end{array}$$

Then we can find a “path” x_{n,l_n} , indexed by $n \in \mathbb{N}$ through the array along which $x_{n,l_n} \rightarrow x$ as $n \rightarrow \infty$. (The point is to move to the right slowly in the array while going down, i.e. $l_n \rightarrow \infty$.) A similar property is valid for sequences of random vectors, where the convergence is taken as convergence in distribution.

3.10 Lemma. For $n, l \in \mathbb{N}$ let $X_{n,l}$ be random vectors such that $X_{n,l} \rightsquigarrow X_l$ as $n \rightarrow \infty$ for every fixed l for random vectors such that $X_l \rightsquigarrow X$ as $l \rightarrow \infty$. Then there exists a sequence $l_n \rightarrow \infty$ such $X_{n,l_n} \rightsquigarrow X$ as $n \rightarrow \infty$.

Proof. Let $D = \{d_1, d_2, \dots\}$ be a countable set that is dense in \mathbb{R}^k and that only contains points at which the distribution functions of the limits X, X_1, X_2, \dots are continuous. Then an arbitrary sequence of random variables Y_n converges in distribution to one of the variables $Y \in \{X, X_1, X_2, \dots\}$ if and only if $P(Y_n \leq d_i) \rightarrow P(Y \leq d_i)$ for every $d_i \in D$. We can prove this using the monotonicity and right-continuity of distribution functions. In turn $P(Y_n \leq d_i) \rightarrow P(Y \leq d_i)$ as $n \rightarrow \infty$ for every $d_i \in D$ if and only if

$$\sum_{i=1}^{\infty} |P(Y_n \leq d_i) - P(Y \leq d_i)| 2^{-i} \rightarrow 0.$$

Now define

$$p_{n,l} = \sum_{i=1}^{\infty} |P(X_{n,l} \leq d_i) - P(X_l \leq d_i)| 2^{-i},$$

$$p_l = \sum_{i=1}^{\infty} |P(X_l \leq d_i) - P(X \leq d_i)| 2^{-i}.$$

The assumptions entail that $p_{n,l} \rightarrow 0$ as $n \rightarrow \infty$ for every fixed l , and that $p_l \rightarrow 0$ as $l \rightarrow \infty$. This implies that there exists a sequence $l_n \rightarrow \infty$ such that $p_{n,l_n} \rightarrow 0$. By the triangle inequality

$$\sum_{i=1}^{\infty} |P(X_{n,l_n} \leq d_i) - P(X \leq d_i)| 2^{-i} \leq p_{n,l_n} + p_{l_n} \rightarrow 0.$$

This implies that $X_{n,l_n} \rightsquigarrow X$ as $n \rightarrow \infty$. ■

3.4 Stochastic o and O symbols

It is convenient to have short expressions for terms that converge in probability to zero or are uniformly tight. The notation $o_P(1)$ (‘small “oh-P-one”’) is short for a sequence of random vectors that converges to zero in probability. The expression $O_P(1)$ (‘big “oh-P-one”’) denotes a sequence that is bounded in probability. More generally, for a given sequence of random variables R_n

$$X_n = o_P(R_n) \quad \text{means} \quad X_n = Y_n R_n \text{ and } Y_n \xrightarrow{P} 0;$$

$$X_n = O_P(R_n) \quad \text{means} \quad X_n = Y_n R_n \text{ and } Y_n = O_P(1).$$

This expresses that the sequence X_n converges in probability to zero or is bounded in probability at ‘rate’ R_n . For deterministic sequences X_n and R_n the stochastic oh-symbols reduce to the usual o and O from calculus.

There are many rules of calculus with o and O symbols, which will be applied without comment. For instance,

$$\begin{aligned} o_P(1) + o_P(1) &= o_P(1) \\ o_P(1) + O_P(1) &= O_P(1) \\ O_P(1)o_P(1) &= o_P(1) \\ (1 + o_P(1))^{-1} &= O_P(1) \\ o_P(R_n) &= R_n o_P(1) \\ O_P(R_n) &= R_n O_P(1) \\ o_P(O_P(1)) &= o_P(1). \end{aligned}$$

To see the validity of these “rules” it suffices to restate them in terms of explicitly named vectors, where each $o_P(1)$ and $O_P(1)$ should be replaced by a different sequence of vectors that converges to zero or is bounded in probability. In this manner the first rule says: if $X_n \xrightarrow{P} 0$ and $Y_n \xrightarrow{P} 0$, then $Z_n = X_n + Y_n \xrightarrow{P} 0$; this is an example of the continuous mapping theorem. The third rule is short for: if X_n is bounded in probability and $Y_n \xrightarrow{P} 0$, then $X_n Y_n \xrightarrow{P} 0$. If X_n would also converge in distribution, then this would be statement (ii) of Slutsky’s lemma (with $c = 0$). But by Prohorov’s theorem X_n converges in distribution “along subsequences” if it is bounded in probability, so that the third rule can still be deduced from Slutsky’s lemma by “arguing along subsequences”.

Note that both rules are in fact implications and should be read from left to right, even though they are stated with the help of the equality “=” sign. Similarly, while it is true that $o_P(1) + o_P(1) = 2o_P(1)$, writing down this rule does not reflect understanding of the o_P -symbol.

Two more complicated rules are given by the following lemma.

3.11 Lemma. *Let R be a function defined on a neighbourhood of $0 \in \mathbb{R}^k$ such that $R(0) = 0$. Let X_n be a sequence of random vectors that converges in probability to zero.*

- (i) *if $R(h) = o(\|h\|)$ as $h \rightarrow 0$, then $R(X_n) = o_P(\|X_n\|)$;*
- (ii) *if $R(h) = O(\|h\|)$ as $h \rightarrow 0$, then $R(X_n) = O_P(\|X_n\|)$.*

Proof. Define $g(h)$ as $g(h) = R(h)/\|h\|$ for $h \neq 0$ and $g(0) = 0$. Then $R(X_n) = g(X_n)\|X_n\|$.

(i). Since the function g is continuous at zero by assumption, $g(X_n) \xrightarrow{P} g(0) = 0$ by the continuous mapping theorem.

(ii). By assumption there exist M and $\delta > 0$ such that $|g(h)| \leq M$ whenever $\|h\| \leq \delta$. Thus $P(|g(X_n)| > M) \leq P(\|X_n\| > \delta) \rightarrow 0$, and the sequence $g(X_n)$ is tight. ■

It should be noted that the rule expressed by the lemma is not a simple plug-in rule. For instance it is not true that $R(h) = o(\|h\|)$ implies that $R(X_n) = o_P(\|X_n\|)$ for every sequence of random vectors X_n .

3.5 Transforms

It is sometimes possible to show convergence in distribution of a sequence of random vectors directly from the definition. In other cases ‘transforms’ of probability measures may help. The basic idea is that it suffices to show characterization (ii) of the portmanteau lemma for a small subset of functions f only.

The most important transform is the *characteristic function*

$$t \mapsto \mathbb{E}e^{it^T X}, \quad t \in \mathbb{R}^k.$$

Each of the functions $x \mapsto e^{it^T x}$ is continuous and bounded. Thus by the portmanteau lemma $\mathbb{E}e^{it^T X_n} \rightarrow \mathbb{E}e^{it^T X}$ for every t if $X_n \rightsquigarrow X$. By Lévy’s continuity theorem the converse is also true: pointwise convergence of characteristic functions is equivalent to weak convergence.

3.12 Theorem (Lévy’s continuity theorem). *Let X_n and X be random vectors in \mathbb{R}^k . Then $X_n \rightsquigarrow X$ if and only if $\mathbb{E}e^{it^T X_n} \rightarrow \mathbb{E}e^{it^T X}$ for every $t \in \mathbb{R}^k$. Moreover, if $\mathbb{E}e^{it^T X_n}$ converges pointwise to a function $\phi(t)$ that is continuous at zero, then ϕ is the characteristic function of a random vector X and $X_n \rightsquigarrow X$.*

The following lemma, which gives a variation on Lévy’s theorem, is less well known, but will be useful in Chapter 4.

3.13 Lemma. *Let X_n be a sequence of random variables such that $\mathbb{E}|X_n|^2 = O(1)$ and such that $\mathbb{E}(iX_n + vt)e^{itX_n} \rightarrow 0$ as $n \rightarrow \infty$, for every $t \in \mathbb{R}$ and some $v > 0$. Then $X_n \rightsquigarrow N(0, v)$.*

Proof. By Markov’s inequality and the bound on the second moments, the sequence X_n is uniformly tight. In view of Prohorov’s theorem it suffices to show that $N(0, v)$ is the only weak limit point.

If $X_n \rightsquigarrow X$ along some sequence of n , then by the boundedness of the second moments and the continuity of the function $x \mapsto (ix + vt)e^{itx}$, we have $\mathbb{E}(iX_n + vt)e^{itX_n} \rightarrow \mathbb{E}(iX + vt)e^{itX}$ for every $t \in \mathbb{R}$. (Cf. Theorem 3.8.) Combining this with the assumption, we see that $\mathbb{E}(iX + vt)e^{itX} = 0$. By Fatou’s lemma $\mathbb{E}X^2 \leq \liminf \mathbb{E}X_n^2 < \infty$ and hence we can differentiate the characteristic function $\phi(t) = \mathbb{E}e^{itX}$ under the expectation to find that $\phi'(t) = \mathbb{E}iXe^{itX}$. We conclude that $\phi'(t) = -vt\phi(t)$. This differential equation possesses $\phi(t) = e^{-vt^2/2}$ as the only solution within the class of characteristic functions. Thus X is normally distributed with mean zero and variance v . ■

3.6 Cramér-Wold Device

The characteristic function $t \mapsto \mathbb{E}e^{it^T X}$ of a vector X is determined by the set of all characteristic functions $u \mapsto \mathbb{E}e^{iu(t^T X)}$ of all linear combinations $t^T X$ of the components

of X . Therefore the continuity theorem implies that weak convergence of vectors is equivalent to weak convergence of linear combinations:

$$X_n \rightsquigarrow X \quad \text{if and only if} \quad t^T X_n \rightsquigarrow t^T X \quad \text{for all } t \in \mathbb{R}^k.$$

This is known as the *Cramér-Wold device*. It allows to reduce all higher dimensional weak convergence problems to the one-dimensional case.

3.14 Example (Multivariate central limit theorem). Let Y, Y_1, Y_2, \dots be i.i.d. random vectors in \mathbb{R}^k with mean vector $\mu = \mathbb{E}Y$ and covariance matrix $\Sigma = \mathbb{E}(Y - \mu)(Y - \mu)^T$. Then

$$\frac{1}{\sqrt{n}} \sum_{i=1}^n (Y_i - \mu) = \sqrt{n}(\bar{Y}_n - \mu) \rightsquigarrow N_k(0, \Sigma).$$

(The sum is taken coordinatewise.) By the Cramér-Wold device the problem can be reduced to finding the limit distribution of the sequences of real-variables

$$t^T \left(\frac{1}{\sqrt{n}} \sum_{i=1}^n (Y_i - \mu) \right) = \frac{1}{\sqrt{n}} \sum_{i=1}^n (t^T Y_i - t^T \mu).$$

Since the random variables $t^T Y_1 - t^T \mu, t^T Y_2 - t^T \mu, \dots$ are i.i.d. with zero mean and variance $t^T \Sigma t$ this sequence is asymptotically $N_1(0, t^T \Sigma t)$ distributed by the univariate central limit theorem. This is exactly the distribution of $t^T X$ if X possesses a $N_k(0, \Sigma)$ distribution. \square

3.7 Delta-method

Let T_n be a sequence of random vectors with values in \mathbb{R}^k and let $\phi: \mathbb{R}^k \rightarrow \mathbb{R}^m$ be a given function defined at least on the range of T_n and a neighbourhood of a vector θ . We shall assume that, for given constants $r_n \rightarrow \infty$, the sequence $r_n(T_n - \theta)$ converges in distribution, and wish to derive a similar result concerning the sequence $r_n(\phi(T_n) - \phi(\theta))$.

Recall that ϕ is *differentiable* at θ if there exists a linear map (matrix) $\phi'_\theta: \mathbb{R}^k \rightarrow \mathbb{R}^m$ such that

$$\phi(\theta + h) - \phi(\theta) = \phi'_\theta(h) + o(\|h\|), \quad h \rightarrow 0.$$

All the expressions in this equation are vectors of length m and $\|h\|$ is the Euclidean norm. The linear map $h \mapsto \phi'_\theta(h)$ is sometimes called a total derivative, as opposed to partial derivatives. A sufficient condition for ϕ to be (totally) differentiable is that all partial derivatives $\partial \phi_j(x) / \partial x_i$ exist for x in a neighbourhood of θ and are continuous at θ . (Just existence of the partial derivatives is not enough.) In any case the total

derivative is found from the partial derivatives. If ϕ is differentiable, then it is partially differentiable and the derivative map $h \mapsto \phi'_\theta(h)$ is matrix multiplication by the matrix

$$\phi'_\theta = \begin{pmatrix} \frac{\partial \phi_1}{\partial x_1}(\theta) & \cdots & \frac{\partial \phi_1}{\partial x_k}(\theta) \\ \vdots & & \vdots \\ \frac{\partial \phi_m}{\partial x_1}(\theta) & \cdots & \frac{\partial \phi_m}{\partial x_k}(\theta) \end{pmatrix}.$$

If the dependence of the derivative ϕ'_θ on θ is continuous, then ϕ is called continuously differentiable.

3.15 Theorem. *Let $\phi: \mathbb{R}^k \rightarrow \mathbb{R}^m$ be a measurable map defined on a subset of \mathbb{R}^k and differentiable at θ . Let T_n be random vectors taking their values in the domain of ϕ . If $r_n(T_n - \theta) \rightsquigarrow T$ for numbers $r_n \rightarrow \infty$, then $r_n(\phi(T_n) - \phi(\theta)) \rightsquigarrow \phi'_\theta(T)$. Moreover, the difference between $r_n(\phi(T_n) - \phi(\theta))$ and $\phi'_\theta(r_n(T_n - \theta))$ converges to zero in probability.*

Proof. Because $r_n \rightarrow \infty$, we have by Slutsky's lemma $T_n - \theta = (1/r_n)r_n(T_n - \theta) \rightsquigarrow 0T = 0$ and hence $T_n - \theta$ converges to zero in probability. Define a function g by

$$g(0) = 0, \quad g(h) = \frac{\phi(\theta + h) - \phi(\theta) - \phi'_\theta(h)}{\|h\|}, \quad \text{if } h \neq 0.$$

Then g is continuous at 0 by the differentiability of ϕ . Therefore, by the continuous mapping theorem, $g(T_n - \theta) \xrightarrow{P} 0$ and hence, by Slutsky's lemma and again the continuous mapping theorem $r_n\|T_n - \theta\|g(T_n - \theta) \xrightarrow{P} \|T\|0 = 0$. Consequently,

$$r_n(\phi(T_n) - \phi(\theta) - \phi'_\theta(T_n - \theta)) = r_n\|T_n - \theta\|g(T_n - \theta) \xrightarrow{P} 0.$$

This yields the last statement of the theorem. Since matrix multiplication is continuous, $\phi'_\theta(r_n(T_n - \theta)) \rightsquigarrow \phi'_\theta(T)$ by the continuous-mapping theorem. Finally, apply Slutsky's lemma to conclude that the sequence $r_n(\phi(T_n) - \phi(\theta))$ has the same weak limit. ■

A common situation is that $\sqrt{n}(T_n - \theta)$ converges to a multivariate normal distribution $N_k(\mu, \Sigma)$. Then the conclusion of the theorem is that the sequence $\sqrt{n}(\phi(T_n) - \phi(\theta))$ converges in law to the $N_m(\phi'_\theta\mu, \phi'_\theta\Sigma(\phi'_\theta)^T)$ distribution.

3.8 Lindeberg Central Limit Theorem

In this section we state, for later reference, a central limit theorem for independent, but not necessarily identically distributed random vectors.

3.16 Theorem (Lindeberg). For each $n \in \mathbb{N}$ let $Y_{n,1}, \dots, Y_{n,n}$ be independent random vectors with finite covariance matrices such that

$$\frac{1}{n} \sum_{i=1}^n \text{Cov } Y_{n,i} \rightarrow \Sigma,$$

$$\frac{1}{n} \sum_{i=1}^n \mathbb{E} \|Y_{n,i}\|^2 \mathbf{1}_{\{\|Y_{n,i}\| > \varepsilon \sqrt{n}\}} \rightarrow 0, \quad \text{for every } \varepsilon > 0.$$

Then the sequence $n^{-1/2} \sum_{i=1}^n (Y_{n,i} - \mathbb{E} Y_{n,i})$ converges in distribution to the normal distribution with mean zero and covariance matrix Σ .

3.9 Minimum Contrast Estimators

Many estimators $\hat{\theta}_n$ of a parameter θ are defined as the point of minimum (or maximum) of a given stochastic process $\theta \mapsto \mathbb{M}_n(\theta)$. In this section we state basic theorems that give the asymptotic behaviour of such *minimum contrast estimators* or *M-estimators* $\hat{\theta}_n$ in the case that the contrast function \mathbb{M}_n fluctuates around a deterministic, smooth function.

Let \mathbb{M}_n be a sequence of stochastic processes indexed by a subset Θ of \mathbb{R}^d , defined on given probability spaces, and let $\hat{\theta}_n$ be random vectors defined on the same probability spaces with values in Θ such that $\mathbb{M}_n(\hat{\theta}_n) \leq \mathbb{M}_n(\theta)$ for every $\theta \in \Theta$. Typically it will be true that $\mathbb{M}_n(\theta) \xrightarrow{P} M(\theta)$ for each θ and a given deterministic function M . Then we may expect that $\hat{\theta}_n \xrightarrow{P} \theta_0$ for θ_0 a point of minimum of the map $\theta \rightarrow M(\theta)$. The following theorem gives a sufficient condition for this. It applies to the more general situation that the “limit” function M is actually a random process.

For a sequence of random variables X_n we write $X_n \xrightarrow{P} 0$ if $X_n > 0$ for every n and $1/X_n = O_P(1)$.

3.17 Theorem. Let \mathbb{M}_n and M_n be stochastic processes indexed by a semi-metric space Θ such that, for some $\theta_0 \in \Theta$,

$$\sup_{\theta \in \Theta} |\mathbb{M}_n(\theta) - M_n(\theta)| \xrightarrow{P} 0,$$

$$\inf_{\theta \in \Theta: d(\theta, \theta_0) > \delta} M_n(\theta) - M_n(\theta_0) \xrightarrow{P} 0.$$

If $\hat{\theta}_n$ are random elements with values in Θ with $\mathbb{M}_n(\hat{\theta}_n) \geq \mathbb{M}_n(\theta_0) - o_P(1)$, then $d(\hat{\theta}_n, \theta_0) \xrightarrow{P} 0$.

Proof. By the uniform convergence to zero of $\mathbb{M}_n - M_n$ and the minimizing property of $\hat{\theta}_n$, we have $M_n(\hat{\theta}_n) = \mathbb{M}_n(\hat{\theta}_n) + o_P(1) \leq \mathbb{M}_n(\theta_0) + o_P(1) = M_n(\theta_0) + o_P(1)$. Write $Z_n(\delta)$

for the left side of the second equation in the display of the theorem. Then $d(\hat{\theta}_n, \theta_0) > \delta$ implies that $M_n(\hat{\theta}_n) - M_n(\theta_0) \geq Z_n(\delta)$. Combined with the preceding this implies that $Z_n(\delta) \leq o_P(1)$. By assumption the probability of this event tends to zero. ■

If the limit criterion function $\theta \rightarrow M(\theta)$ is smooth and takes its minimum at the point θ_0 , then its first derivative must vanish at θ_0 , and the second derivative V must be positive definite. Thus it possesses a parabolic approximation $M(\theta) = M(\theta_0) + \frac{1}{2}(\theta - \theta_0)^T V(\theta - \theta_0)$ around θ_0 . The random criterion function \mathbb{M}_n can be thought of as the limiting criterion function plus the random perturbation $\mathbb{M}_n - M$ and possesses approximation

$$\mathbb{M}_n(\theta) - \mathbb{M}_n(\theta_0) \approx \frac{1}{2}(\theta - \theta_0)^T V(\theta - \theta_0) + [(\mathbb{M}_n - M)(\theta) - (\mathbb{M}_n - M)(\theta_0)].$$

We shall assume that the term in square brackets possesses a linear approximation of the form $(\theta - \theta_0)^T Z_n / \sqrt{n}$. If we ignore all the remainder terms and minimize the quadratic form

$$\theta - \theta_0 \mapsto \frac{1}{2}(\theta - \theta_0)^T V(\theta - \theta_0) + (\theta - \theta_0)^T Z_n / \sqrt{n}$$

over $\theta - \theta_0$, then we find that the minimum is taken for $\theta - \theta_0 = -V^{-1}Z_n / \sqrt{n}$. Thus we expect that the M -estimator $\hat{\theta}_n$ satisfies $\sqrt{n}(\hat{\theta}_n - \theta_0) = -V^{-1}Z_n + o_P(1)$. This derivation is made rigorous in the following theorem.

3.18 Theorem. *Let \mathbb{M}_n be stochastic processes indexed by an open subset Θ of Euclidean space and let $M: \Theta \rightarrow \mathbb{R}$ be a deterministic function. Assume that $\theta \rightarrow M(\theta)$ is twice continuously differentiable at a point of minimum θ_0 with nonsingular second-derivative matrix V .[‡] Suppose that*

$$\begin{aligned} r_n(\mathbb{M}_n - M)(\tilde{\theta}_n) - r_n(\mathbb{M}_n - M)(\theta_0) \\ = (\tilde{\theta}_n - \theta_0)' Z_n + o_P^*(\|\tilde{\theta}_n - \theta_0\| + r_n\|\tilde{\theta}_n - \theta_0\|^2 + r_n^{-1}), \end{aligned}$$

for every random sequence $\tilde{\theta}_n = \theta_0 + o_P^*(1)$ and a uniformly tight sequence of random vectors Z_n . If the sequence $\hat{\theta}_n$ converges in outer probability to θ_0 and satisfies $\mathbb{M}_n(\hat{\theta}_n) \leq \inf_{\theta} \mathbb{M}_n(\theta) + o_P(r_n^{-2})$ for every n , then

$$r_n(\hat{\theta}_n - \theta_0) = -V^{-1}Z_n + o_P^*(1).$$

If it is known that the sequence $r_n(\hat{\theta}_n - \theta_0)$ is uniformly tight, then the displayed condition needs to be verified for sequences $\tilde{\theta}_n = \theta_0 + O_P^*(r_n^{-1})$ only.

Proof. The stochastic differentiability condition of the theorem together with the two-times differentiability of the map $\theta \rightarrow M(\theta)$ yields for every sequence $\tilde{h}_n = o_P^*(1)$

$$\begin{aligned} (3.1) \quad \mathbb{M}_n(\theta_0 + \tilde{h}_n) - \mathbb{M}_n(\theta_0) &= \frac{1}{2}\tilde{h}_n' V \tilde{h}_n + r_n^{-1}\tilde{h}_n' Z_n \\ &\quad + o_P^*(\|\tilde{h}_n\|^2 + r_n^{-1}\|\tilde{h}_n\| + r_n^{-2}). \end{aligned}$$

[‡] It suffices that a two-term Taylor expansion is valid at θ_0 .

For \tilde{h}_n chosen equal to $\hat{h}_n = \hat{\theta}_n - \theta_0$, the left side (and hence the right side) is at most $o_P(r_n^{-2})$ by the definition of $\hat{\theta}_n$. In the right side the term $\tilde{h}_n' V \tilde{h}_n$ can be bounded below by $c \|\tilde{h}_n\|^2$ for a positive constant c , since the matrix V is strictly positive definite. Conclude that

$$c \|\hat{h}_n\|^2 + r_n^{-1} \|\hat{h}_n\| O_P(1) + o_P(\|\hat{h}_n\|^2 + r_n^{-2}) \leq o_P(r_n^{-2}).$$

Complete the square to see that this implies that

$$(c + o_P(1)) \left(\|\hat{h}_n\| - O_P(r_n^{-1}) \right)^2 \leq O_P(r_n^{-2}).$$

This can be true only if $\|\hat{h}_n\| = O_P^*(r_n^{-1})$.

For any sequence \tilde{h}_n of the order $O_P^*(r_n^{-1})$, the three parts of the remainder term in (3.1) are of the order $o_P(r_n^{-2})$. Apply this with the choices \hat{h}_n and $-r_n^{-1} V^{-1} Z_n$ to conclude that

$$\begin{aligned} \mathbb{M}_n(\theta_0 + \hat{h}_n) - \mathbb{M}_n(\theta_0) &= \frac{1}{2} \hat{h}_n' V \hat{h}_n + r_n^{-1} \hat{h}_n' Z_n + o_P^*(r_n^{-2}), \\ \mathbb{M}_n(\theta_0 - r_n^{-1} V^{-1} Z_n) - \mathbb{M}_n(\theta_0) &= -\frac{1}{2} r_n^{-2} Z_n' V^{-1} Z_n + o_P^*(r_n^{-2}). \end{aligned}$$

The left-hand side of the first equation is smaller than the second, up to an $o_P^*(r_n^{-2})$ -term. Subtract the second equation from the first to find that

$$\frac{1}{2} (\hat{h}_n + r_n^{-1} V^{-1} Z_n)' V (\hat{h}_n + r_n^{-1} V^{-1} Z_n) \leq o_P(r_n^{-2}).$$

Since V is strictly positive definite, this yields the first assertion of the theorem.

If it is known that the sequence $\hat{\theta}_n$ is r_n -consistent, then the middle part of the preceding proof is unnecessary and we can proceed to inserting \hat{h}_n and $-r_n^{-1} V^{-1} Z_n$ in (3.1) immediately. The latter equation is then needed for sequences $\tilde{h}_n = O_P^*(r_n^{-1})$ only. ■

4

Central Limit Theorem

The classical central limit theorem asserts that the mean of independent, identically distributed random variables with finite variance is asymptotically normally distributed. In this chapter we extend this to dependent variables.

Given a stationary time series X_t let $\bar{X}_n = n^{-1} \sum_{t=1}^n X_t$ be the *average* of the variables X_1, \dots, X_n . If μ and γ_X are the mean and auto-covariance function of the time series, then, by the usual rules for expectation and variance,

$$\begin{aligned} \text{E}\bar{X}_n &= \mu, \\ (4.1) \quad \text{var}(\sqrt{n}\bar{X}_n) &= \frac{1}{n} \sum_{s=1}^n \sum_{t=1}^n \text{cov}(X_s, X_t) = \sum_{h=-n}^n \left(\frac{n-|h|}{n} \right) \gamma_X(h). \end{aligned}$$

In the expression for the variance every of the terms $(n-|h|)/n$ is bounded by 1 and converges to 1 as $n \rightarrow \infty$. If $\sum |\gamma_X(h)| < \infty$, then we can apply the dominated convergence theorem and obtain that $\text{var}(\sqrt{n}\bar{X}_n) \rightarrow \sum_h \gamma_X(h)$. In any case

$$(4.2) \quad \text{var} \sqrt{n}\bar{X}_n \leq \sum_h |\gamma_X(h)|.$$

Hence absolute convergence of the series of auto-covariances implies that the sequence $\sqrt{n}(\bar{X}_n - \mu)$ is uniformly tight. The purpose of the chapter is to give conditions for this sequence to be asymptotically normally distributed with mean zero and variance $\sum_h \gamma_X(h)$.

Such conditions are of two types: martingale and mixing.

The martingale central limit theorem is concerned with time series such that the sums $\sum_{t=1}^n X_t$ form a martingale. It thus makes a structural assumption on the expected value of the increments X_t of these sums given the past variables.

Mixing conditions, in a general sense, require that elements X_t and X_{t+h} at large time lags h be approximately independent. Positive and negative values of deviations $X_t - \mu$ at large time lags will then occur independently and partially cancel each other, which is the intuitive reason for normality of sums. Absolute convergence of the series $\sum_h \gamma_X(h)$,

which is often called *short-range dependence*, can be viewed as a mixing condition, as it implies that covariances at large lags are small. However, it is not strong enough to imply a central limit theorem. Finitely dependent time series and linear processes are special examples of mixing time series that do satisfy the central limit theorem. We also discuss a variety of general “mixing” conditions.

- * **4.1 EXERCISE.** Suppose that the series $v := \sum_h \gamma_X(h)$ converges (not necessarily absolutely). Show that $\text{var } \sqrt{n} \bar{X}_n \rightarrow v$. [Write $\text{var } \sqrt{n} \bar{X}_n$ as \bar{v}_n for $v_h = \sum_{|j| < h} \gamma_X(j)$ and apply Cesaro’s lemma: if $v_n \rightarrow v$, then $\bar{v}_n \rightarrow v$.]

4.1 Finite Dependence

A time series X_t is called *m-dependent* if the random vectors (\dots, X_{t-1}, X_t) and $(X_{t+m+1}, X_{t+m+2}, \dots)$ are independent for every $t \in \mathbb{Z}$. In other words, “past” and “future” are independent if m “present” variables are left out.

4.2 EXERCISE. Show that the moving average $X_t = Z_t + \theta Z_{t-1}$ considered in Example 1.6, with Z_t an i.i.d. sequence, is 1-dependent.

4.3 EXERCISE. Show that “0-dependent” is equivalent to “independent”.

4.4 Theorem. Let X_t be a strictly stationary, m -dependent time series with mean zero and finite variance. Then the sequence $\sqrt{n} \bar{X}_n$ converges in distribution to a normal distribution with mean 0 and variance $\sum_h \gamma_X(h)$.

Proof. Choose a (large) integer l and divide X_1, \dots, X_n into $r = \lfloor n/l \rfloor$ groups of size l and a remainder group of size $n - rl < l$. Let $A_{1,l}, \dots, A_{r,l}$ and $B_{1,l}, \dots, B_{r,l}$ be the sums of the first $l - m$ and last m of the variables X_i in the r groups. (Cf. Figure 4.1.) Then both $A_{1,l}, \dots, A_{r,l}$ and $B_{1,l}, \dots, B_{r,l}$ are sequences of independent identically distributed random variables (but the two sequences may be dependent) and

$$(4.3) \quad \sum_{i=1}^n X_i = \sum_{j=1}^r A_{j,l} + \sum_{j=1}^r B_{j,l} + \sum_{i=rl+1}^n X_i.$$

We shall show that for suitable $l = l_n \rightarrow \infty$, the second and third terms tend to zero, whereas the first tends to a normal distribution.

For fixed l and $n \rightarrow \infty$ (hence $r \rightarrow \infty$) the classical central limit theorem applied to the variables $A_{j,l}$ yields

$$\frac{1}{\sqrt{n}} \sum_{j=1}^r A_{j,l} = \sqrt{\frac{r}{n}} \frac{1}{\sqrt{r}} \sum_{j=1}^r A_{j,l} \rightsquigarrow \frac{1}{\sqrt{l}} N(0, \text{var } A_{1,l}).$$

Next the variables $n^{-1/2} \sum_{i=rl+1}^n X_i$ have mean zero, and by the triangle inequality, for fixed l as $n \rightarrow \infty$,

$$\text{sd}\left(\frac{1}{\sqrt{n}} \sum_{i=rl+1}^n X_i\right) \leq \frac{l}{\sqrt{n}} \text{sd}(X_1) \rightarrow 0.$$

By Chebyshev's inequality it follows that the third term in (4.3) tends to zero in probability. We conclude by Slutsky's lemma that, as $n \rightarrow \infty$,

$$S_{n,l} := \frac{1}{\sqrt{n}} \sum_{j=1}^r A_{j,l} + \frac{1}{\sqrt{n}} \sum_{i=rl+1}^n X_i \rightsquigarrow N\left(0, \frac{1}{l} \text{var } A_{1,l}\right).$$

This is true for every fixed l . If $l \rightarrow \infty$, then

$$\frac{1}{l} \text{var } A_{1,l} = \frac{1}{l} \text{var} \sum_{i=1}^{l-m} X_i = \sum_{h=m-l}^{l-m} \frac{l-m-|h|}{l} \gamma_X(h) \rightarrow \sum_{h=-m}^m \gamma_X(h) =: v.$$

Therefore, by Lemma 3.10 there exists a sequence $l_n \rightarrow \infty$ such that $S_{n,l_n} \rightsquigarrow N(0, v)$.

Let $r_n = \lfloor n/l_n \rfloor$ be the corresponding sequence of values of r_n , so that $r_n/n \rightarrow 0$. By the strict stationarity of the series X_t each $B_{j,l}$ is equal in distribution to $X_1 + \dots + X_m$. Hence $\text{var } B_{j,l}$ is independent of j and l and, by the independence of $B_{1,l}, \dots, B_{r,l}$,

$$\mathbb{E}\left(\frac{1}{\sqrt{n}} \sum_{j=1}^{r_n} B_{j,l_n}\right)^2 = \frac{r_n}{n} \text{var } B_{1,l_n} \rightarrow 0.$$

Thus the sequence of random variables in the left side converges to zero in probability, by Chebyshev's inequality.

In view of (4.3) another application of Slutsky's lemma gives the result. ■

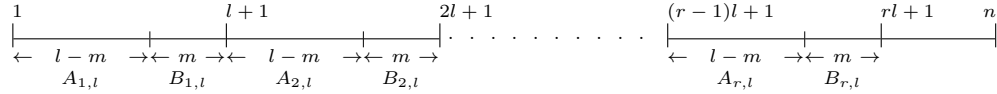

Figure 4.1. Blocking of observations in the proof of Theorem 4.4.

4.2 Linear Processes

A *linear process* is a time series that can be represented as an infinite moving average

$$(4.4) \quad X_t = \mu + \sum_{j=-\infty}^{\infty} \psi_j Z_{t-j},$$

for a sequence $\dots, Z_{-1}, Z_0, Z_1, Z_2, \dots$ of independent and identically distributed variables with $EZ_t = 0$, a constant μ , and constants ψ_j with $\sum_j |\psi_j| < \infty$. This may seem special, but we shall see later that this includes, for instance, the rich class of all ARMA-processes.

By (iii) of Lemma 1.29 the covariance function of a linear process is given by $\gamma_X(h) = \sigma^2 \sum_j \psi_j \psi_{j+h}$, where $\sigma^2 = \text{var } Z_t$, and hence the asymptotic variance of $\sqrt{n}\bar{X}_n$ is given by

$$(4.5) \quad v := \sum_h \gamma_X(h) = \sigma^2 \sum_h \sum_j \psi_j \psi_{j+h} = \sigma^2 \left(\sum_j \psi_j \right)^2.$$

4.5 Theorem. *Suppose that (4.4) holds for an i.i.d. sequence Z_t with mean zero and finite variance and numbers ψ_j with $\sum_j |\psi_j| < \infty$. Then the sequence $\sqrt{n}(\bar{X}_n - \mu)$ converges in distribution to a normal distribution with mean zero and variance v .*

Proof. We can assume without loss of generality that $\mu = 0$. For a fixed (large) integer m define the time series

$$X_t^m = \sum_{|j| \leq m} \psi_j Z_{t-j} = \sum_j \psi_j^m Z_{t-j},$$

where $\psi_j^m = \psi_j$ if $|j| \leq m$ and 0 otherwise. Then X_t^m is $2m$ -dependent and strictly stationary. By Theorem 4.4, the sequence $\sqrt{n}\bar{X}_n^m$ converges as $n \rightarrow \infty$ in distribution to a normal distribution with mean zero and variance (see (4.5))

$$v_m := \sum_h \gamma_{X^m}(h) = \sigma^2 \left(\sum_j \psi_j^m \right)^2 = \sigma^2 \left(\sum_{|j| \leq m} \psi_j \right)^2.$$

As $m \rightarrow \infty$ this converges to v . Because $N(0, v_m) \rightsquigarrow N(0, v)$, Lemma 3.10 guarantees the existence of a sequence $m_n \rightarrow \infty$ such that $\sqrt{n}\bar{X}_n^{m_n} \rightsquigarrow N(0, v)$.

In view of Slutsky's lemma the proof will be complete once we have shown that $\sqrt{n}(\bar{X}_n - \bar{X}_n^{m_n}) \xrightarrow{P} 0$. This concerns the average $\bar{Y}_n^{m_n}$ of the differences $Y_t^m = X_t - X_t^m = \sum_{|j| > m} \psi_j Z_{t-j}$. These satisfy

$$E(\sqrt{n}\bar{X}_n - \sqrt{n}\bar{X}_n^{m_n})^2 = \text{var } \sqrt{n}\bar{Y}_n^{m_n} \leq \sum_h |\gamma_{Y^{m_n}}(h)| \leq \sigma^2 \left(\sum_{|j| > m_n} |\psi_j| \right)^2.$$

The inequalities follow by (4.1) and Lemma 1.29(iii). The right side converges to zero as $m_n \rightarrow \infty$. ■

4.3 Strong Mixing

The α -mixing coefficients (or *strong mixing coefficients*) of a time series X_t are defined by $\alpha(0) = \frac{1}{2}$ and for $h \in \mathbb{N}^b$

$$\alpha(h) = 2 \sup_t \sup_{\substack{A \in \sigma(\dots, X_{t-1}, X_t) \\ B \in \sigma(X_{t+h}, X_{t+h+1}, \dots)}} |\mathbb{P}(A \cap B) - \mathbb{P}(A)\mathbb{P}(B)|.$$

The events A and B in this display depend on elements X_t of the “past” and “future”, respectively, that are h time lags apart. Thus the α -mixing coefficients measure the extent by which events A and B that are separated by h time instants *fail* to satisfy the equality $\mathbb{P}(A \cap B) = \mathbb{P}(A)\mathbb{P}(B)$, which is valid for independent events. If the series X_t is strictly stationary, then the supremum over t is unnecessary, and the mixing coefficient $\alpha(h)$ can be defined using the σ -fields $\sigma(\dots, X_{-1}, X_0)$ and $\sigma(X_h, X_{h+1}, \dots)$ only.

It is immediate from their definition that the coefficients $\alpha(1), \alpha(2), \dots$ are decreasing and nonnegative. Furthermore, if the time series is m -dependent, then $\alpha(h) = 0$ for $h > m$.

4.6 EXERCISE. Show that $\alpha(1) \leq \frac{1}{2} \equiv \alpha(0)$. [Apply the inequality of Cauchy-Schwarz to $\mathbb{P}(A \cap B) - \mathbb{P}(A)\mathbb{P}(B) = \text{cov}(1_A, 1_B)$.]

Warning. The mixing numbers $\alpha(h)$ are denoted by the same symbol as the partial auto-correlations $\alpha_X(h)$.

If $\alpha(h) \rightarrow 0$ as $h \rightarrow \infty$, then the time series X_t is called α -mixing or *strong mixing*. Then events connected to time sets that are far apart are “approximately independent”. For a central limit theorem to hold, the convergence to 0 must take place at a sufficient speed, dependent on the “sizes” of the variables X_t .

A precise formulation can best be given in terms of the inverse function of the mixing coefficients. We can extend α to a function $\alpha: [0, \infty) \rightarrow [0, 1]$ by defining it to be constant on the intervals $[h, h+1)$ for integers h . This yields a monotone, right-continuous function that decreases in steps from $\alpha(0) = \frac{1}{2}$ to 0 at infinity in the case that the time series is mixing. The generalized inverse $\alpha^{-1}: [0, 1] \rightarrow [0, \infty)$ is defined by

$$\alpha^{-1}(u) = \inf\{x \geq 0: \alpha(x) \leq u\} = \sum_{h=0}^{\infty} 1_{u < \alpha(h)}.$$

Alternatively, we can define $\alpha^{-1}(u) = h$ iff $\alpha(h) \leq u < \alpha(h-1)$. Similarly, the quantile function F_X^{-1} of a random variable X is the (usual) generalized inverse of the distribution function F_X of X , and is given by

$$F_X^{-1}(1-u) = \inf\{x \in \mathbb{R}: 1 - F_X(x) \leq u\}.$$

Both functions $u \mapsto \alpha^{-1}(u)$ and $u \mapsto F_X^{-1}(1-u)$ are decreasing.

^b We denote by $\sigma(X_t: t \in I)$ the σ -field generated by the set of random variables $\{X_t: t \in I\}$.

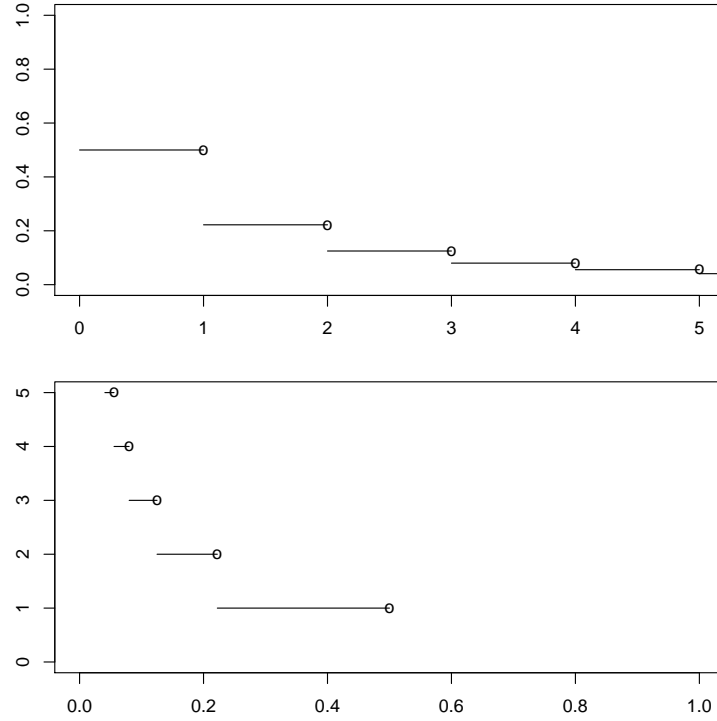

Figure 4.2. Typical functions α (top panel) and α^{-1} (bottom panel).

4.7 Theorem. *If X_t is a strictly stationary time series with mean zero such that $\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du < \infty$, then the series $v = \sum_h \gamma_X(h)$ converges absolutely and $\sqrt{n} \bar{X}_n \rightsquigarrow N(0, v)$.*

The condition of the theorem is a little complicated, because it combines the requirements that the mixing coefficients converge to zero fast enough and that the tails of the variables X_t are not too heavy. Loosening one of the two more may be compensated by making the other requirement more stringent. To make this concrete we can derive finiteness of the integral under a combination of a mixing and a moment condition, as expressed in the following corollary.

4.8 Corollary (Ibragimov). *If X_t is a strictly stationary time series with mean zero such that $E|X_0|^r < \infty$ and $\sum_h \alpha(h)^{1-2/r} < \infty$ for some $r > 2$, then the series $v = \sum_h \gamma_X(h)$ converges absolutely and $\sqrt{n} \bar{X}_n \rightsquigarrow N(0, v)$.*

Proof. If $c^r := E|X_0|^r < \infty$ for some $r > 2$, then $1 - F_{|X_0|}(x) \leq c^r/x^r$ by Markov's

inequality and hence $F_{|X_0|}^{-1}(1-u) \leq c/u^{1/r}$. Then we obtain the bound

$$\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du \leq \sum_{h=0}^{\infty} \int_0^1 1_{u < \alpha(h)} \frac{c^2}{u^{2/r}} du = \frac{c^2 r}{r-2} \sum_{h=0}^{\infty} \alpha(h)^{1-2/r}.$$

The right side is finite by assumption, and hence the integral condition of Theorem 4.7 is satisfied. ■

The corollary assumes finiteness of the r th moment $E|X_0|^r$ and convergence of the series of the $(1-2/r)$ th powers of the mixing coefficients. For larger values of r the moment condition is more restrictive, but the mixing condition is weaker. The intuition is that heavy tailed distributions occasionally produce big values $|X_t|$. Combined with strong dependence, this may lead to clusters of big variables, which will influence the average \bar{X}_n relatively strongly, and prevent its approximate normality.

4.9 EXERCISE (Case $r = \infty$). Show that $\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du$ is bounded above by $\|X_0\|_{\infty}^2 \sum_{h=0}^{\infty} \alpha(h)$. [Note that $F_{|X_0|}^{-1}(1-U)$ is distributed as $|X_0|$ if U is uniformly distributed.]

4.10 EXERCISE. Show that $\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du \leq (m+1)EX_0^2$ if the time series X_t is m -dependent. Recover Theorem 4.4 from Theorem 4.7.

4.11 EXERCISE. Show that $\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du < \infty$ implies that $E|X_0|^2 < \infty$.

The key to the proof of Theorem 4.7 is a lemma that bounds covariances in terms of mixing coefficients. Let $\|X\|_p$ denote the L_p -norm of a random variable X , i.e.

$$\|X\|_p = (E|X|^p)^{1/p}, \quad 1 \leq p < \infty, \quad \|X\|_{\infty} = \inf\{M: P(|X| \leq M) = 1\}.$$

Recall *Hölder's inequality*: for any pair of numbers $p, q > 0$ (possibly infinite) with $p^{-1} + q^{-1} = 1$ and random variables X and Y

$$E|XY| \leq \|X\|_p \|Y\|_q.$$

For $p = q = 2$ this is precisely the inequality of Cauchy-Schwarz. The other case of interest to us is the combination $p = 1, q = \infty$, for which the inequality is immediate. By repeated application the inequality can be extended to more than two random variables. For instance, for any numbers $p, q, r > 0$ with $p^{-1} + q^{-1} + r^{-1} = 1$ and random variables X, Y , and Z

$$E|XYZ| \leq \|X\|_p \|Y\|_q \|Z\|_r.$$

4.12 Lemma (Covariance bound). *Let X_t be a time series with α -mixing coefficients $\alpha(h)$ and let Y and Z be random variables that are measurable relative to $\sigma(\dots, X_{-1}, X_0)$ and $\sigma(X_h, X_{h+1}, \dots)$, respectively, for a given $h \geq 0$. Then, for any $p, q, r > 0$ such that $p^{-1} + q^{-1} + r^{-1} = 1$,*

$$|\text{cov}(Y, Z)| \leq 2 \int_0^{\alpha(h)} F_{|Y|}^{-1}(1-u) F_{|Z|}^{-1}(1-u) du \leq 2\alpha(h)^{1/p} \|Y\|_q \|Z\|_r.$$

Proof. By the definition of the mixing coefficients, we have, for every $y, z > 0$,

$$|\text{cov}(1_{Y > y}, 1_{Z > z})| \leq \frac{1}{2} \alpha(h).$$

The same inequality is valid with Y^+ and/or Z^+ replaced by Y^- and/or Z^- . By bilinearity of the covariance and the triangle inequality,

$$|\text{cov}(1_{Y > y} - 1_{Y^- > y}, 1_{Z > z} - 1_{Z^- > z})| \leq 2\alpha(h).$$

Because $|\text{cov}(U, V)| \leq 2E|U| \|V\|_\infty$ for any pair of random variables U, V (by the simplest Hölder inequality), we obtain that the covariance on the left side of the preceding display is also bounded by $2(P(Y^+ > y) + P(Y^- > y)) = 2(1 - F_{|Y|})(y)$. Yet another bound for the covariance is obtained by interchanging the roles of Y and Z . Combining the three inequalities, we see that, for any $y, z > 0$, the left side of the preceding display is bounded above by

$$2[\alpha(h) \wedge (1 - F_{|Y|})(y) \wedge (1 - F_{|Z|})(z)] = 2 \int_0^{\alpha(h)} 1_{1 - F_{|Y|}(y) > u} 1_{1 - F_{|Z|}(z) > u} du.$$

Next we write $Y = Y^+ - Y^- = \int_0^\infty (1_{Y > y} - 1_{Y^- > y}) dy$ and similarly for Z , to obtain, by Fubini's theorem,

$$\begin{aligned} |\text{cov}(Y, Z)| &= \left| \int_0^\infty \int_0^\infty \text{cov}(1_{Y > y} - 1_{Y^- > y}, 1_{Z > z} - 1_{Z^- > z}) dy dz \right| \\ &\leq 2 \int_0^\infty \int_0^\infty \int_0^{\alpha(h)} 1_{F_{|Y|}(y) < 1-u} 1_{F_{|Z|}(z) < 1-u} du dy dz. \end{aligned}$$

Any pair of a distribution function F and a quantile function F^{-1} satisfies $F(x) < u$ if and only $x < F^{-1}(u)$, for every x and u . Hence $\int_0^\infty 1_{F(x) < 1-u} dx = F^{-1}(1-u)$, and we conclude the proof of the first inequality of the lemma by another application of Fubini's theorem.

The second inequality follows upon noting that $F_{|Y|}^{-1}(1-U)$ is distributed as $|Y|$ if U is uniformly distributed on $[0, 1]$, and next applying Hölder's inequality. ■

Taking Y and Z in the lemma to X_0 and X_h , respectively, for a stationary time series X_t , and (p, q, r) equal to $(r/(r-2), r, r)$ for some $r \geq 4$, we see that

$$|\gamma_X(h)| \leq 2 \int_0^{\alpha(h)} F_{|X_0|}^{-1}(1-u)^2 du \leq 2\alpha(h)^{1-2/r} \|X_0\|_r^2.$$

Consequently, we find that

$$\sum_{h \geq 0} |\gamma_X(h)| \leq 2 \sum_{h \geq 0} \int_0^{\alpha(h)} F_{|X_0|}^{-1}(1-u)^2 du = 2 \int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du.$$

This proves the first assertion of Theorem 4.7. Furthermore, in view of (4.2) and the symmetry of the auto-covariance function,

$$(4.6) \quad \text{var } \sqrt{n} \bar{X}_n \leq 4 \int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du.$$

We defer the remainder of the proof of Theorem 4.7 to the end of the chapter.

* 4.4 Uniform Mixing

There are several other types of mixing coefficients. The ϕ -mixing coefficients or *uniform mixing coefficients* of a strictly stationary time series X_t are defined by

$$\begin{aligned} \phi(h) &= \sup_{\substack{A \in \sigma(\dots, X_{-1}, X_0), P(A) \neq 0 \\ B \in \sigma(X_h, X_{h+1}, \dots)}} |P(B|A) - P(B)|, \\ \tilde{\phi}(h) &= \sup_{\substack{A \in \sigma(\dots, X_{-1}, X_0) \\ B \in \sigma(X_h, X_{h+1}, \dots), P(B) \neq 0}} |P(A|B) - P(A)|. \end{aligned}$$

It is immediate from the definitions that $\alpha(h) \leq 2(\phi(h) \wedge \tilde{\phi}(h))$. Thus a ϕ -mixing time series is always α -mixing. It appears that conditions in terms of ϕ -mixing are often much more restrictive, even though there is no complete overlap.

4.13 Lemma (Covariance bound). *Let X_t be a strictly stationary time series with ϕ -mixing coefficients $\phi(h)$ and $\tilde{\phi}(h)$ and let Y and Z be random variables that are measurable relative to $\sigma(\dots, X_{-1}, X_0)$ and $\sigma(X_h, X_{h+1}, \dots)$, respectively, for a given $h \geq 0$. Then, for any $p, q > 0$ with $p^{-1} + q^{-1} = 1$,*

$$|\text{cov}(Y, Z)| \leq 2\phi(h)^{1/p} \tilde{\phi}(h)^{1/q} \|Y\|_p \|Z\|_q.$$

Proof. Let Q be the measure $P^{Y,Z} - P^Y \otimes P^Z$ on \mathbb{R}^2 , and let $|Q|$ be its absolute value. Then

$$|\text{cov}(Y, Z)| = \left| \iint yz dQ(y, z) \right| \leq \left(\iint |y|^p dQ(y, z) \right)^{1/p} \left(\iint |z|^q dQ(y, z) \right)^{1/q},$$

by Hölder's inequality. It suffices to show that the first and second marginals of $|Q|$ are bounded above by the measures $2\phi(h)P^Y$ and $2\tilde{\phi}(h)P^Z$, respectively. By symmetry it suffices to consider the first marginal.

By definition we have that

$$|Q|(C) = \sup_D \left(|Q(C \cap D)| + |Q(C \cap D^c)| \right)$$

for the supremum taken over all Borel sets D in \mathbb{R}^2 . Equivalently, we can compute the supremum over any algebra that generates the Borel sets. In particular, we can use the algebra consisting of all finite unions of rectangles $A \times B$. Conclude from this that

$$|Q|(C) = \sup \sum_i \sum_j |Q(C \cap (A_i \times B_j))|,$$

for the supremum taken over all pairs of partitions $\mathbb{R} = \cup_i A_i$ and $\mathbb{R} = \cup_j B_j$. It follows that

$$\begin{aligned} |Q|(A \times \mathbb{R}) &= \sup \sum_i \sum_j |Q((A \cap A_i) \times B_j)| \\ &= \sup \sum_i \sum_j |P^{Z|Y}(B_j | A \cap A_i) - P^Z(B_j)| P^Y(A \cap A_i). \end{aligned}$$

If, for fixed i , B_i^+ consists of the union of all B_j such that $P^{Z|Y}(B_j | A \cap A_i) - P^Z(B_j) > 0$ and B_i^- is the union of the remaining B_j , then the double sum can be rewritten

$$\sum_i \left(|P^{Z|Y}(B_i^+ | A \cap A_i) - P^Z(B_i^+)| + |P^{Z|Y}(B_i^- | A \cap A_i) - P^Z(B_i^-)| \right) P^Y(A \cap A_i).$$

The sum between round brackets is bounded above by $2\phi(h)$, by the definition of ϕ . Thus the display is bounded above by $2\phi(h)P^Y(A)$. ■

4.14 Theorem. *If X_t is a strictly stationary time series with mean zero such that $E|X_t|^{p \vee q} < \infty$ and $\sum_h \phi(h)^{1/p} \tilde{\phi}(h)^{1/q} < \infty$ for some $p, q > 0$ with $p^{-1} + q^{-1} = 1$, then the series $v = \sum_h \gamma_X(h)$ converges absolutely and $\sqrt{n}\bar{X}_n \rightsquigarrow N(0, v)$.*

Proof. For a given $M > 0$ let $X_t^M = X_t 1\{|X_t| \leq M\}$ and let $Y_t^M = X_t - X_t^M$. Because X_t^M is a measurable transformation of X_t , it is immediate from the definition of the mixing coefficients that Y_t^M is mixing with smaller mixing coefficients than X_t . Therefore, by (4.2) and Lemma 4.13,

$$\text{var } \sqrt{n}(\bar{X}_n - \bar{X}_n^M) \leq 2 \sum_h \phi(h)^{1/p} \tilde{\phi}(h)^{1/q} \|Y_0^M\|_p \|Y_0^M\|_q.$$

As $M \rightarrow \infty$, the right side converges to zero, and hence the left side converges to zero, uniformly in n . This means that we can reduce the problem to the case of uniformly bounded time series X_t , as in the proof of Theorem 4.7.

Because the α -mixing coefficients are bounded above by the ϕ -mixing coefficients, we have that $\sum_h \alpha(h) < \infty$. Therefore, the second part of the proof of Theorem 4.7 applies without changes. ■

4.5 Martingale Differences

The *martingale central limit theorem* applies to the special time series for which the partial sums $\sum_{t=1}^n X_t$ are a martingale (as a process in n), or equivalently the increments X_t are “martingale differences”. In Score processes (derivatives of log likelihoods) will be an important example of application in Chapter 13.

The martingale central limit theorem can be seen as another type of generalization of the ordinary central limit theorem. The partial sums of an i.i.d. sequence grow by increments X_t that are independent from the “past”. The classical central limit theorem shows that this induces asymptotic normality, provided that the increments are centered and not too big (finite variance suffices). The mixing central limit theorems relax the independence to near independence of variables at large time lags, a condition that involves the whole distribution. In contrast, the martingale central limit theorem imposes conditions on the conditional first and second moments of the increments given the past, without directly involving other aspects of the distribution. In this sense it is closer to the ordinary central limit theorem. The first moments given the past are assumed zero; the second moments given the past must not be too big.

The “past” can be given by an arbitrary filtration. A *filtration* \mathcal{F}_t is a nondecreasing collection of σ -fields $\cdots \subset \mathcal{F}_{-1} \subset \mathcal{F}_0 \subset \mathcal{F}_1 \subset \cdots$. The σ -field \mathcal{F}_t can be thought of as the “events that are known” at time t . Often it will be the σ -field generated by the variables $X_t, X_{t-1}, X_{t-2}, \dots$; the corresponding filtration is called the *natural filtration* of the time series X_t , or the *filtration generated by* this series. A *martingale difference series* relative to a given filtration is a time series X_t such that, for every t :

- (i) X_t is \mathcal{F}_t -measurable;
- (ii) $E(X_t | \mathcal{F}_{t-1}) = 0$.

The second requirement implicitly includes the assumption that $E|X_t| < \infty$, so that the conditional expectation is well defined; the identity is understood to be in the almost-sure sense.

4.15 EXERCISE. Show that a martingale difference series with finite variances is a white noise series.

4.16 Theorem. If X_t is a martingale difference series relative to the filtration \mathcal{F}_t such that $n^{-1} \sum_{t=1}^n E(X_t^2 | \mathcal{F}_{t-1}) \xrightarrow{P} v$ for a positive constant v , and such that $n^{-1} \sum_{t=1}^n E(X_t^2 1_{|X_t| > \varepsilon \sqrt{n}} | \mathcal{F}_{t-1}) \xrightarrow{P} 0$ for every $\varepsilon > 0$, then $\sqrt{n} \bar{X}_n \rightsquigarrow N(0, v)$.

Proof. For simplicity of notation, let E_t denote conditional expectation given \mathcal{F}_{t-1} . Because the events $A_t = \{n^{-1} \sum_{j=1}^t E_{j-1} X_j^2 \leq 2v\}$ are \mathcal{F}_{t-1} -measurable, the variables

$X_{n,t} = n^{-1/2} X_t 1_{A_t}$ are martingale differences relative to the filtration \mathcal{F}_t . They satisfy

$$(4.7) \quad \begin{aligned} \sum_{t=1}^n \mathbb{E}_{t-1} X_{n,t}^2 &\leq 2v, \\ \sum_{t=1}^n \mathbb{E}_{t-1} X_{n,t}^2 &\xrightarrow{\mathbb{P}} v, \\ \sum_{t=1}^n \mathbb{E}_{t-1} X_{n,t}^2 1_{|X_{n,t}| > \varepsilon} &\xrightarrow{\mathbb{P}} 0, \quad \text{every } \varepsilon > 0. \end{aligned}$$

To see this note first that $\mathbb{E}_{t-1} X_{n,t}^2 = 1_{A_t} n^{-1} \mathbb{E}_{t-1} X_t^2$, and that the events A_t are decreasing: $A_1 \supset A_2 \supset \dots \supset A_n$. The first relation in the display follows from the definition of the events A_t , which make that the cumulative sums stop increasing before they cross the level $2v$. The second relation follows, because the left side of this relation is equal to $n^{-1} \sum_{t=1}^n \mathbb{E}_{t-1} X_t^2$ on A_n , which tends to v by assumption, and the probability of the event A_n tends to 1 by assumption. The third relation is immediate from the conditional Lindeberg assumption on the X_t and the fact that $|X_{n,t}| \leq X_t/\sqrt{n}$, for every t .

On the event A_n we also have that $X_{n,t} = X_t/\sqrt{n}$ for every $t = 1, \dots, n$ and hence the theorem is proved once it has been established that $\sum_{t=1}^n X_{n,t} \rightsquigarrow N(0, v)$.

We have that $|e^{ix} - 1 - ix| \leq x^2/2$ for every $x \in \mathbb{R}$. Furthermore, the function $R: \mathbb{R} \rightarrow \mathbb{C}$ defined by $e^{ix} - 1 - ix + x^2/2 = x^2 R(x)$ satisfies $|R(x)| \leq 1$ and $R(x) \rightarrow 0$ as $x \rightarrow 0$. If $\delta, \varepsilon > 0$ are chosen such that $|R(x)| < \varepsilon$ if $|x| \leq \delta$, then $|e^{ix} - 1 - ix + x^2/2| \leq x^2 1_{|x| > \delta} + \varepsilon x^2$. For fixed $u \in \mathbb{R}$ define

$$R_{n,t} = \mathbb{E}_{t-1}(e^{iuX_{n,t}} - 1 - iuX_{n,t}).$$

It follows that $|R_{n,t}| \leq \frac{1}{2}u^2 \mathbb{E}_{t-1} X_{n,t}^2$ and

$$\begin{aligned} \sum_{t=1}^n |R_{n,t}| &\leq \frac{1}{2}u^2 \sum_{t=1}^n \mathbb{E}_{t-1} X_{n,t}^2 \leq u^2 v, \\ \max_{1 \leq t \leq n} |R_{n,t}| &\leq \frac{1}{2}u^2 \left(\sum_{t=1}^n \mathbb{E}_{t-1} X_{n,t}^2 1_{|X_{n,t}| > \delta} + \delta^2 \right), \\ \sum_{t=1}^n |R_{n,t} + \frac{1}{2}u^2 \mathbb{E}_{t-1} X_{n,t}^2| &\leq u^2 \sum_{t=1}^n \left(\mathbb{E}_{t-1} X_{n,t}^2 1_{|X_{n,t}| > \delta} + \varepsilon \mathbb{E}_{t-1} X_{n,t}^2 \right). \end{aligned}$$

The second and third inequalities together with (4.7) imply that the sequence $\max_{1 \leq t \leq n} |R_{n,t}|$ tends to zero in probability and that the sequence $\sum_{t=1}^n R_{n,t}$ tends in probability to $-\frac{1}{2}u^2 v$.

The function $\tilde{S}: \mathbb{R} \rightarrow \mathbb{R}$ defined by $\log(1-x) = -x + x\tilde{S}(x)$ satisfies $\tilde{S}(x) \rightarrow 0$ as $x \rightarrow 0$. It follows that $\max_{1 \leq t \leq n} |\tilde{S}(R_{n,t})| \xrightarrow{\mathbb{P}} 0$, and

$$\prod_{t=1}^n (1 - R_{n,t}) = e^{\sum_{t=1}^n \log(1-R_{n,t})} = e^{-\sum_{t=1}^n R_{n,t} + \sum_{t=1}^n R_{n,t} \tilde{S}(R_{n,t})} \xrightarrow{\mathbb{P}} e^{u^2 v/2}.$$

We also have that $\prod_{t=1}^k |1 - R_{n,t}| \leq \exp \sum_{t=1}^n |R_{n,t}| \leq e^{u^2 v}$, for every $k \leq n$. Therefore, by the dominated convergence theorem, the convergence in the preceding display is also in absolute mean.

For every t ,

$$\begin{aligned} E_{n-1} e^{iuX_{n,n}} (1 - R_{n,n}) &= (1 - R_{n,n}) E_{n-1} (e^{iuX_{n,n}} - 1 - iuX_{n,n} + 1) \\ &= (1 - R_{n,n})(R_{n,n} + 1) = 1 - R_{n,n}^2. \end{aligned}$$

Therefore, by conditioning on \mathcal{F}_{n-1} ,

$$E \prod_{t=1}^n e^{iuX_{n,t}} (1 - R_{n,t}) = E \prod_{t=1}^{n-1} e^{iuX_{n,t}} (1 - R_{n,t}) - E \prod_{t=1}^{n-1} e^{iuX_{n,t}} (1 - R_{n,t}) R_{n,n}^2.$$

By repeating this argument, we find that

$$\left| E \prod_{t=1}^n e^{iuX_{n,t}} (1 - R_{n,t}) - 1 \right| = \left| - \sum_{k=1}^n E \prod_{t=1}^{k-1} e^{iuX_{n,t}} (1 - R_{n,t}) R_{n,k}^2 \right| \leq e^{u^2 v} E \sum_{t=1}^n R_{n,t}^2.$$

This tends to zero, because $\sum_{t=1}^n |R_{n,t}|$ is bounded above by a constant and $\max_{1 \leq t \leq n} |R_{n,t}|$ tends to zero in probability.

We combine the results of the last two paragraphs to conclude that

$$\left| E \prod_{t=1}^n e^{iuX_{n,t}} e^{u^2 v/2} - 1 \right| = \left| E \prod_{t=1}^n e^{iuX_{n,t}} e^{u^2 v/2} - \prod_{t=1}^n e^{iuX_{n,t}} (1 - R_{n,t}) \right| + o(1) \rightarrow 0.$$

The theorem follows from the continuity theorem for characteristic functions. ■

Apart from the structural condition that the sums $\sum_{t=1}^n X_t$ form a martingale, the martingale central limit theorem requires that the sequence of variables $Y_t = E(X_t^2 | \mathcal{F}_{t-1})$ satisfies a law of large numbers and that the variables $Y_{t,\varepsilon,n} = E(X_t^2 1_{|X_t| > \varepsilon \sqrt{n}} | \mathcal{F}_{t-1})$ satisfy a (conditional) Lindeberg-type condition. These conditions are immediate for “ergodic” sequences, which by definition are (strictly stationary) sequences for which any integrable “running transformation” of the type $Y_t = g(X_t, X_{t-1}, \dots)$ satisfies the Law of Large Numbers. The concept of ergodicity is discussed at length in Section 7.2.

4.17 Corollary. *If X_t is a strictly stationary, ergodic martingale difference series relative to its natural filtration with mean zero and $v = EX_t^2 < \infty$, then $\sqrt{n} \bar{X}_n \rightsquigarrow N(0, v)$.*

Proof. By strict stationarity there exists a fixed measurable function $g: \mathbb{R}^\infty \rightarrow \mathbb{R}^\infty$ such that $E(X_t^2 | X_{t-1}, X_{t-2}, \dots) = g(X_{t-1}, X_{t-2}, \dots)$ almost surely, for every t . The ergodicity of the series X_t is inherited by the series $Y_t = g(X_{t-1}, X_{t-2}, \dots)$ and hence $\bar{Y}_n \rightarrow EY_1 = EX_1^2$ almost surely. By a similar argument the averages $n^{-1} \sum_{t=1}^n E(X_t^2 1_{|X_t| > M} | \mathcal{F}_{t-1})$ converge almost surely to their expectation, for every fixed M . This expectation can be made arbitrarily small by choosing M large. For any fixed $\varepsilon > 0$ the sequence $n^{-1} \sum_{t=1}^n E(X_t^2 1_{\{|X_t| > \varepsilon \sqrt{n}\}} | \mathcal{F}_{t-1})$ is bounded by this sequence eventually, for any given M , and hence converges almost surely to zero. ■

* 4.6 Projections

Let X_t be a centered time series and $\mathcal{F}_0 = \sigma(X_0, X_{-1}, \dots)$. For a suitably mixing time series the covariance $E(X_n E(X_j | \mathcal{F}_0))$ between X_n and the best prediction of X_j at time 0 should be small as $n \rightarrow \infty$. The following theorem gives a precise and remarkably simple sufficient condition for the central limit theorem in terms of these quantities.

4.18 Theorem. *let X_t be a strictly stationary, mean zero, ergodic time series with $\sum_h |\gamma_X(h)| < \infty$ and, as $n \rightarrow \infty$,*

$$\sum_{j=0}^{\infty} |E(X_n E(X_j | \mathcal{F}_0))| \rightarrow 0.$$

Then $\sqrt{n}\bar{X}_n \rightsquigarrow N(0, v)$, for $v = \sum_h \gamma_X(h)$.

Proof. For a fixed integer m define a time series

$$Y_{t,m} = \sum_{j=t}^{t+m} (E(X_j | \mathcal{F}_t) - E(X_j | \mathcal{F}_{t-1})).$$

Then $Y_{t,m}$ is a strictly stationary martingale difference series. By the ergodicity of the series X_t , for fixed m as $n \rightarrow \infty$,

$$\frac{1}{n} \sum_{t=1}^n E(Y_{t,m}^2 | \mathcal{F}_{t-1}) \rightarrow EY_{0,m}^2 =: v_m,$$

almost surely and in mean. The number v_m is finite, because the series X_t is square-integrable by assumption. By the martingale central limit theorem, Theorem 4.16, we conclude that $\sqrt{n}\bar{Y}_{n,m} \rightsquigarrow N(0, v_m)$ as $n \rightarrow \infty$, for every fixed m .

Because $X_t = E(X_t | \mathcal{F}_t)$ we can write

$$\begin{aligned} \sum_{t=1}^n (Y_{t,m} - X_t) &= \sum_{t=1}^n \sum_{j=t+1}^{t+m} E(X_j | \mathcal{F}_t) - \sum_{t=1}^n \sum_{j=t}^{t+m} E(X_j | \mathcal{F}_{t-1}) \\ &= \sum_{j=n+1}^{n+m} E(X_j | \mathcal{F}_n) - \sum_{j=1}^m E(X_j | \mathcal{F}_0) - \sum_{t=1}^n E(X_{t+m} | \mathcal{F}_{t-1}). \end{aligned}$$

Write the right side as $Z_{n,m} - Z_{0,m} - R_{n,m}$. Then the time series $Z_{t,m}$ is stationary with

$$EZ_{0,m}^2 = \sum_{i=1}^m \sum_{j=1}^m E(E(X_i | \mathcal{F}_0) E(X_j | \mathcal{F}_0)) \leq m^2 EX_0^2.$$

The right side divided by n converges to zero as $n \rightarrow \infty$, for every fixed m . Furthermore,

$$\begin{aligned} ER_{n,m}^2 &= \sum_{s=1}^n \sum_{t=1}^n \mathbb{E} \left(\mathbb{E}(X_{s+m} | \mathcal{F}_{s-1}) \mathbb{E}(X_{t+m} | \mathcal{F}_{t-1}) \right) \\ &\leq 2 \sum_{1 \leq s \leq t \leq n} \mathbb{E}(\mathbb{E}(X_{s+m} | \mathcal{F}_{s-1}) X_{t+m}) \\ &\leq 2n \sum_{h=1}^{\infty} |\mathbb{E} \mathbb{E}(X_{m+1} | \mathcal{F}_0) X_{h+m}| = 2n \sum_{h=m+1}^{\infty} |\mathbb{E} X_{m+1} \mathbb{E}(X_h | \mathcal{F}_0)|. \end{aligned}$$

The right side divided by n converges to zero as $m \rightarrow \infty$. Combining the three preceding displays we see that the sequence $\sqrt{n}(\bar{Y}_{n,m} - \bar{X}_n) = (Z_{n,m} - Z_{0,m} - R_{n,m})/\sqrt{n}$ converges to zero in second mean as $n \rightarrow \infty$ followed by $m \rightarrow \infty$.

Because $Y_{t,m}$ is a martingale difference series, the variables $Y_{t,m}$ are uncorrelated and hence

$$\text{var } \sqrt{n} \bar{Y}_{n,m} = \mathbb{E} Y_{0,m}^2 = v_m.$$

Because, as usual, $\text{var } \sqrt{n} \bar{X}_n \rightarrow v$ as $n \rightarrow \infty$, combination with the preceding paragraph shows that $v_m \rightarrow v$ as $m \rightarrow \infty$. Consequently, by Lemma 3.10 there exists $m_n \rightarrow \infty$ such that $\sqrt{n} Y_{n,m_n} \rightsquigarrow N(0, v)$ and $\sqrt{n}(Y_{n,m_n} - \bar{X}_n) \rightsquigarrow 0$. This implies the theorem in view of Slutsky's lemma. ■

4.19 EXERCISE. Derive the martingale central limit theorem, Theorem 4.16, from Theorem 4.18. [The infinite sum is really equal to $|\mathbb{E} X_n X_0|$]

* 4.7 Proof of Theorem 4.7

In this section we present two proofs of Theorem 4.7, the first based on characteristic functions and Lemma 3.13, and the second based on Theorem 4.18.

Proof of Theorem 4.7 (first version). For a given $M > 0$ let $X_t^M = X_t 1\{|X_t| \leq M\}$ and let $Y_t^M = X_t - X_t^M$. Because X_t^M is a measurable transformation of X_t , it is immediate from the definition of the mixing coefficients that the series Y_t^M is mixing with smaller mixing coefficients than the series X_t . Therefore, in view of (4.6)

$$\text{var } \sqrt{n}(\bar{X}_n - \bar{X}_n^M) = \text{var } \sqrt{n} \bar{Y}_n^M \leq 4 \int_0^1 \alpha^{-1}(u) F_{|Y_0^M|}^{-1}(1-u)^2 du.$$

Because $Y_0^M = 0$ whenever $|X_0| \leq M$, it follows that $Y_0^M \rightsquigarrow 0$ as $M \rightarrow \infty$ and hence $F_{|Y_0^M|}^{-1}(u) \rightarrow 0$ for every $u \in (0, 1)$. Furthermore, because $|Y_0^M| \leq |X_0|$, its quantile function is bounded above by the quantile function of $|X_0|$. By the dominated convergence theorem the integral in the preceding display converges to zero as $M \rightarrow \infty$, and hence

the variance in the left side converges to zero as $M \rightarrow \infty$, uniformly in n . If we can show that $\sqrt{n}(\bar{X}_n^M - EX_0^M) \rightsquigarrow N(0, v^M)$ as $n \rightarrow \infty$ for $v^M = \lim \text{var } \sqrt{n} \bar{X}_n^M$ and every fixed M , then it follows that $\sqrt{n}(\bar{X}_n - EX_0) \rightsquigarrow N(0, v)$ for $v = \lim v^M = \lim \text{var } \sqrt{n} \bar{X}_n$, by Lemma 3.10, and the proof is complete.

Thus it suffices to prove the theorem for uniformly bounded variables X_t . Let M be the uniform bound.

Fix some sequence $m_n \rightarrow \infty$ such that $\sqrt{n}\alpha(m_n) \rightarrow 0$ and $m_n/\sqrt{n} \rightarrow 0$. Such a sequence exists. To see this, first note that $\sqrt{n}\alpha(\lfloor \sqrt{n}/k \rfloor) \rightarrow 0$ as $n \rightarrow \infty$, for every fixed k . (See Problem 4.20). Thus by Lemma 3.10 there exists $k_n \rightarrow \infty$ such that $\sqrt{n}\alpha(\lfloor \sqrt{n}/k_n \rfloor) \rightarrow 0$ as $k_n \rightarrow \infty$. Now set $m_n = \lfloor \sqrt{n}/k_n \rfloor$. For simplicity write m for m_n . Also let it be silently understood that all summation indices are restricted to the integers $1, 2, \dots, n$, unless indicated otherwise.

Let $S_n = n^{-1/2} \sum_{t=1}^n X_t$ and, for every given t , set $S_n(t) = n^{-1/2} \sum_{|j-t|<m} X_j$. Because $|e^{i\lambda} - 1 - i\lambda| \leq \frac{1}{2}\lambda^2$ for every $\lambda \in \mathbb{R}$, we have

$$\begin{aligned} \left| \mathbb{E} \left[\frac{1}{\sqrt{n}} \sum_{t=1}^n X_t e^{i\lambda S_n} \left(e^{-i\lambda S_n(t)} - 1 + i\lambda S_n(t) \right) \right] \right| &\leq \frac{\lambda^2 n M}{2\sqrt{n}} \sum_{t=1}^n \mathbb{E} S_n^2(t) \\ &= \frac{\lambda^2 M}{2\sqrt{n}} \sum_{t=1}^n \sum_{|i-t|<m} \sum_{|j-t|<m} \gamma_X(i-j) \\ &\leq \frac{\lambda^2 M}{2\sqrt{n}} m \sum_h |\gamma_X(h)| \rightarrow 0. \end{aligned}$$

Furthermore, with $A_n(t)$ and $B_n(t)$ defined as $n^{-1/2}$ times the sum of the X_j with $1 \leq j \leq t-m$ and $t+m \leq j \leq n$, respectively, we have $S_n - S_n(t) = A_n(t) + B_n(t)$ and

$$\begin{aligned} &\left| \mathbb{E} \left(\frac{1}{\sqrt{n}} \sum_{t=1}^n X_t e^{i\lambda S_n} e^{-i\lambda S_n(t)} \right) \right| \\ &\leq \frac{1}{\sqrt{n}} \sum_{t=1}^n \left| \text{cov}(X_t e^{i\lambda A_n(t)}, e^{i\lambda B_n(t)}) + \text{cov}(X_t, e^{i\lambda A_n(t)}) \mathbb{E} e^{i\lambda B_n(t)} \right| \\ &\leq 4\sqrt{n} M \alpha(m) \rightarrow 0, \end{aligned}$$

by the second inequality of Lemma 4.12, with $p = 1$ and $q = r = \infty$. Combining the preceding pair of displays we see that

$$\mathbb{E} S_n e^{i\lambda S_n} = \mathbb{E} \frac{1}{\sqrt{n}} \sum_{t=1}^n X_t e^{i\lambda S_n} i\lambda S_n(t) + o(1) = i\lambda \mathbb{E} \left(e^{i\lambda S_n} \frac{1}{n} \sum_{|s-t|<m} \sum X_s X_t \right) + o(1).$$

If we can show that $n^{-1} \sum_{|s-t|<m} X_s X_t$ converges in mean to v , then the right side of the last display is asymptotically equivalent to $i\lambda \mathbb{E} e^{i\lambda S_n} v$, and the theorem is proved in view of Lemma 3.13.

In fact, we show that $n^{-1} \sum \sum_{|s-t|<m} X_s X_t \rightarrow v$ in second mean. First,

$$E \frac{1}{n} \sum \sum_{|s-t|<m} X_s X_t = \sum_{|h|<m} \left(\frac{n-|h|}{n} \right) \gamma_X(h) \rightarrow v,$$

By the dominated convergence theorem, in view of (4.2). Second,

$$\text{var} \left(\frac{1}{n} \sum \sum_{|s-t|<m} X_s X_t \right) \leq \frac{1}{n^2} \sum \sum_{|s-t|<m} \sum \sum_{|i-j|<m} |\text{cov}(X_s X_t, X_i X_j)|.$$

The first double sum on the right can be split in the sums over the pairs (s, t) with $s < t$ and $s \geq t$, respectively, and similarly for the second double sum relative to (i, j) . By symmetry the right side is bounded by

$$\begin{aligned} & \frac{4}{n^2} \sum \sum_{\substack{|s-t|<m \\ s \leq t}} \sum \sum_{\substack{|i-j|<m \\ i \leq j}} |\text{cov}(X_s X_t, X_i X_j)| \\ & \leq \frac{4}{n^2} \sum_{s=1}^n \sum_{t=0}^m \sum_{i=1}^n \sum_{j=0}^m |\text{cov}(X_s X_{s+t}, X_i X_{i+j})| \\ & \leq \frac{8}{n^2} \sum_{s=1}^n \sum_{t=0}^m \sum_{i=1}^n \sum_{j=0}^m |\text{cov}(X_s X_{s+t}, X_{s+i} X_{s+i+j})|, \end{aligned}$$

by the same argument, this time splitting the sums over $s \leq i$ and $s > i$ and using symmetry between s and i . If $i \geq t$, then the covariance in the sum is bounded above by $2\alpha(i-t)M^4$, by Lemma 4.12, because there are $i-t$ time instants between $X_s X_{s+t}$ and $X_{s+i} X_{s+i+j}$. If $i < t$, then we rewrite the absolute covariance as

$$\left| \text{cov}(X_s, X_{s+t} X_{s+i} X_{s+i+j}) - \text{cov}(X_s, X_{s+t}) E X_{s+i} X_{s+i+j} \right| \leq 4\alpha(i)M^4.$$

Thus the four-fold sum is bounded above by

$$\frac{32}{n^2} \sum_{s=1}^n \sum_{t=0}^m \sum_{i=1}^n \sum_{j=0}^m \left(\alpha(i-t)M^4 1_{i \geq t} + \alpha(i)M^4 1_{i < t} \right) \leq 64M^4 \frac{m^2}{n} \sum_{i \geq 0} \alpha(i).$$

Because $F_{|X_0|}^{-1}$ is bounded away from zero in a neighbourhood of 0, finiteness of the integral $\int_0^1 \alpha^{-1}(u) F_{|X_0|}^{-1}(1-u)^2 du$ implies that the series on the right converges. This conclude the proof. ■

* **4.20 EXERCISE.** Suppose that $\alpha(h)$ is a decreasing sequence of nonnegative numbers ($h = 1, 2, \dots$) with $\sum_h \alpha(h) < \infty$. Show that $h\alpha(h) \rightarrow 0$ as $h \rightarrow \infty$. [First derive, using the monotonicity, that $\sum_h 2^h \alpha(2^h) < \infty$ and conclude from this that $2^h \alpha(2^h) \rightarrow 0$. Next use the monotonicity again “to fill the gaps”.]

Proof of Theorem 4.7 (second version). Let ΔF denote the jump sizes of a cumulative distribution function F . For $Y_n = E(X_n | \mathcal{F}_0)$ and V a uniform variable independent of

the other variables, set

$$1 - U_n = F_{|Y_n|}(|Y_n| -) + V \Delta F_{|Y_n|}(|Y_n|),$$

This definition is an extended form of the probability integral transformation, allowing for jumps in the distribution function. The variable U_n is uniformly distributed and $F_{|Y_n|}^{-1}(1 - U_n) = |Y_n|$ almost surely. Because Y_n is \mathcal{F}_0 -measurable the covariance inequality, Lemma 4.12, gives

$$\begin{aligned} |\mathbb{E}(\mathbb{E}(X_n | \mathcal{F}_0) X_j)| &\leq 2 \int_0^{\alpha_j} F_{|Y_n|}^{-1}(1 - u) F_{|X_j|}^{-1}(1 - u) du \\ &= 2 \mathbb{E} Y_n \operatorname{sign}(Y_n) F_{|X_j|}^{-1}(1 - U_n) 1_{U_n < \alpha_j} \\ &= 2 \mathbb{E} X_n \operatorname{sign}(Y_n) F_{|X_j|}^{-1}(1 - U_n) 1_{U_n < \alpha_j} \\ &\leq 2 \mathbb{E} |X_n| F_{|X_j|}^{-1}(1 - U_n) 1_{U_n < \alpha_j} \\ &\leq 4 \int_0^1 F_{|X_n|}^{-1}(1 - u) G^{-1}(1 - u) du \end{aligned}$$

by a second application of Lemma 4.12, with $\alpha = 1$ and G the distribution function of the random variable $F_{|X_j|}^{-1}(1 - U_n) 1_{U_n < \alpha_j}$. The corresponding quantile function $G^{-1}(1 - u)$ vanishes off $[0, \alpha_j]$ and is bounded above by the quantile function of $|X_j|$. Therefore, the expression is further bounded by $\int_0^{\alpha_j} F_{|X_0|}^{-1}(1 - u)^2 du$. We finish by summing up over j . ■

Nonparametric Estimation of Mean and Covariance

Suppose we observe the values X_1, \dots, X_n from the stationary time series X_t with mean $\mu_X = EX_t$, covariance function $h \mapsto \gamma_X(h)$, and correlation function $h \mapsto \rho_X(h)$. If nothing is known about the distribution of the time series, besides that it is stationary, then “obvious” estimators for these parameters are

$$\begin{aligned}\hat{\mu}_n &= \bar{X}_n = \frac{1}{n} \sum_{t=1}^n X_t, \\ \hat{\gamma}_n(h) &= \frac{1}{n} \sum_{t=1}^{n-h} (X_{t+h} - \bar{X}_n)(X_t - \bar{X}_n), \quad (0 \leq h < n), \\ \hat{\rho}_n(h) &= \frac{\hat{\gamma}_n(h)}{\hat{\gamma}_n(0)}.\end{aligned}$$

These estimators are called *nonparametric*, because they are not motivated by a statistical model that restricts the distribution of the time series. Their advantage is that they work for (almost) every stationary time series. Better estimators, in particular for γ_X and ρ_X , might exist given a specific (and valid) statistical model for the time series. We shall see examples when discussing ARMA-processes in Chapter 8.

- * **5.1 EXERCISE.** The factor $1/n$ in the definition of $\hat{\gamma}_n(h)$ is sometimes replaced by $1/(n-h)$, because there are $n-h$ terms in the sum. Show that with the present definition of $\hat{\gamma}_n$ the corresponding estimator $(\hat{\gamma}_n(s-t))_{s,t=1,\dots,h}$ for the covariance matrix of (X_1, \dots, X_h) is nonnegative-definite. Show by example that this is not true if we use $1/(n-h)$. [Write the matrix as QQ^T for a suitable $(n \times (2n))$ matrix Q .]

The time series X_t is called *Gaussian* if the joint distribution of any finite number of the variables X_t is multivariate-normal. In that case \bar{X}_n is normally distributed. The distributions of $\hat{\gamma}_n(h)$ and $\hat{\rho}_n(h)$ are complicated, even under normality. Distributional statements considering these estimators are therefore usually asymptotic in nature, as

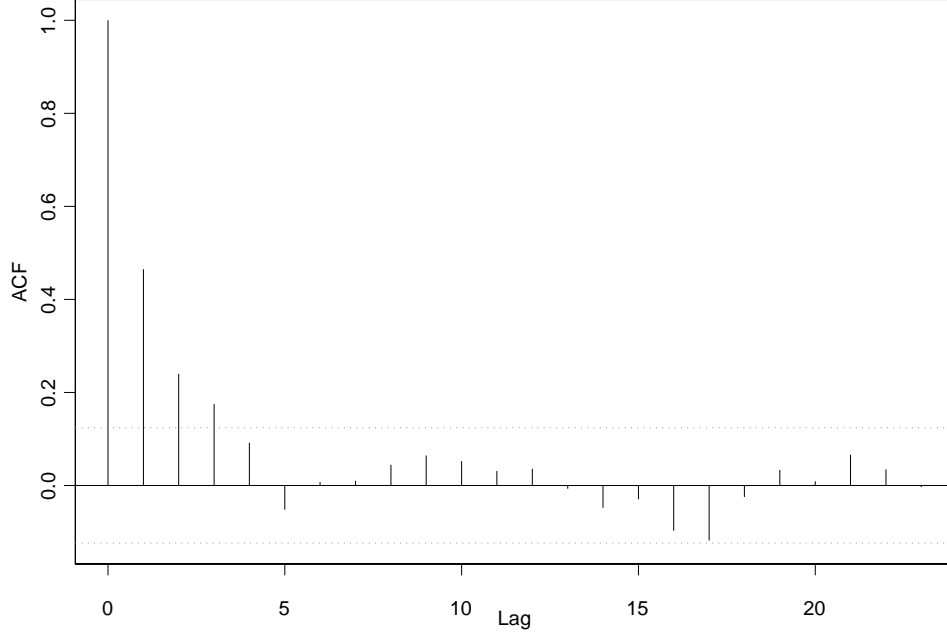

Figure 5.1. Realization of the sample auto-correlation function ($n = 250$) of the stationary time series satisfying $X_{t+1} = 0.5X_t + Z_t$ for standard normal white noise Z_t .

$n \rightarrow \infty$. In this chapter we discuss conditions under which the three estimators are asymptotically normally distributed. This knowledge can be used to set approximate confidence intervals.

5.1 Mean

The asymptotic normality of the sample mean is the subject of Chapter 4. The statistical significance of the central limit theorem is that the sample mean is an asymptotically *consistent* estimator of the true mean μ_X , with precision of the order $1/\sqrt{n}$. The central limit theorem can be used in a preciser way to derive an asymptotic confidence interval for μ_X . This requires an estimator of the (asymptotic) variance of the sample mean, which we discuss in this section.

An approximate confidence interval for μ_X based on the sample mean typically takes the form

$$\left(\bar{X}_n - \frac{\hat{\sigma}_n}{\sqrt{n}} 1.96, \bar{X}_n + \frac{\hat{\sigma}_n}{\sqrt{n}} 1.96 \right).$$

If $\sqrt{n}(\bar{X}_n - \mu_X)/\hat{\sigma}_n \rightsquigarrow N(0, 1)$ as $n \rightarrow \infty$, then the confidence level of this interval converges to 95%. The problem is to find suitable estimators $\hat{\sigma}_n$.

If the sequence $\sqrt{n}(\bar{X}_n - \mu_X)$ is asymptotically normal, as it is under the conditions of the preceding chapter, the procedure works if the $\hat{\sigma}_n$ are consistent estimators of the (asymptotic) variance of \bar{X}_n . However, constructing such estimators is not a trivial matter. Unlike in the case of independent, identically distributed variables, the variance of the sample mean depends on characteristics of the joint distribution of (X_1, \dots, X_n) , rather than only on the marginal distributions (see (4.1)). The limiting variance $\sum_h \gamma_X(h)$ depends even on the joint distribution of the infinite sequence (X_1, X_2, \dots) . With a sufficient number of observations it is possible to estimate the auto-covariances $\gamma_X(h)$ at smaller lags h , but, without further information, this is not true for larger lags $h \approx n$ (let alone $h \geq n$), unless we make special assumptions. Setting a confidence interval is therefore much harder than in the case of independent, identically distributed variables.

If a reliable model is available, expressed in a vector of parameters, then the problem can be solved by a *model-based estimator*: the variance of the sample mean is expressed in the parameters, which are next replaced by estimators. If there are not too many parameters in the model this should be feasible. (Methods to estimate parameters are discussed in later chapters.)

5.2 EXERCISE.

- (i) Calculate the asymptotic variance of the sample mean for the moving average $X_t = Z_t + \theta Z_{t-1}$.
- (ii) Same question for the stationary solution of $X_t = \phi X_{t-1} + Z_t$, where $|\phi| < 1$.

However, the use of a model-based estimator is at odds with the theme of this chapter: nonparametric estimation. We now discuss several methods of nonparametric estimation that work as soon as the time series is sufficiently mixing.

In common use is the method of *batched means*. The total set of observations is split into r blocks

$$[X_1, \dots, X_l], [X_{l+1}, \dots, X_{2l}], \dots, [X_{(r-1)l+1}, \dots, X_{rl}]$$

of l observations each. (Assume that $n = rl$ for simplicity; drop a last batch of fewer than l observations, for simplicity.) If Y_1, \dots, Y_r are the sample means of the r blocks, then $\bar{Y}_r = \bar{X}_n$ and hence $\text{var } \bar{Y}_r = \text{var } \bar{X}_n$. The hope is that we can ignore the dependence between Y_1, \dots, Y_r and can simply estimate the variance $\text{var}(\sqrt{r}\bar{Y}_r) = (r/n) \text{var}(\sqrt{n}\bar{X}_n)$ by the sample variance $S_{r,Y}^2$ of Y_1, \dots, Y_r . If l is “large enough” and the original series X_t is sufficiently mixing, then this actually works, to some extent.

Presumably, the method of batched means uses disjoint blocks of X_t in order to achieve the approximate independence of the block means Y_1, \dots, Y_r . In general these are still dependent. This does not cause much (additional) bias in the estimator of the variance, but it may have an effect on the precision. It turns out that it is better to use *all* blocks of l consecutive X_t , even though these may be more dependent. Thus in our second method we consider all blocks

$$[X_1, \dots, X_l], [X_2, \dots, X_{l+1}], \dots, [X_{n-l+1}, \dots, X_n]$$

of l consecutive observations. We let $Z_{n,1}, Z_{n,2}, \dots, Z_{n,n-l+1}$ be the sample means of the $n-l+1$ blocks, so that $l \operatorname{var} Z_{n,i} = \operatorname{var}(\sqrt{l}\bar{X}_l) \approx \operatorname{var}(\sqrt{n}\bar{X}_n)$, if l is large. This suggests to estimate the variance of $\sqrt{n}\bar{X}_n$ by $lS_{n-l+1,Z}^2$. The following theorem shows that this method works under some conditions, provided that l is chosen dependent on n with $l_n \rightarrow \infty$ at a not too fast rate. The theorem considers both the sample variance of the (recentered) block means,

$$\tilde{S}_{n,Z}^2 = \frac{1}{n-l_n+1} \sum_{i=1}^{n-l_n+1} (Z_{n,i} - \bar{X}_n)^2,$$

and the *empirical distribution function* of the centered and scaled block means,

$$F_n(x) = \frac{1}{n-l_n+1} \sum_{i=1}^{n-l_n+1} 1\{\sqrt{l_n}(Z_{n,i} - \bar{X}_n) \leq x\}.$$

The function F_n is the cumulative distribution function of the discrete distribution that puts mass $1/(n-l_n+1)$ at each centered and scaled block mean $\sqrt{l_n}(Z_{n,i} - \bar{X}_n)$. The second moment of this distribution is $l_n \tilde{S}_{n,Z}^2$. We have centered the block means at the average \bar{X}_n of the full sample, which is not unnatural, but slightly different from the average \bar{Z}_l of the block means, making $\tilde{S}_{n,Z}^2$ deviate slightly from the sample variance. Exercise 5.4 indicates the difference is negligible.

The following theorem shows that the sequence F_n tends weakly to the same limit as the sequence $\sqrt{n}(\bar{X}_n - \mu_X)$, and its second moments $l_n \tilde{S}_{n,Z}^2$ converge as well.

5.3 Theorem. *Suppose that the time series X_t is strictly stationary and α -mixing with mixing coefficients satisfying $\sum_h \alpha(h) < \infty$. Let $l_n \rightarrow \infty$ such that $l_n/n \rightarrow 0$. Furthermore, suppose that $\sqrt{n}(\bar{X}_n - \mu_X) \rightsquigarrow N(0, v)$, for some number v . Then, for every x , the sequence $F_n(x)$ converges in probability to $\Phi(x/\sqrt{v})$. Furthermore, if $v = \sum_h \gamma_X(h)$, then the second moments $l_n \tilde{S}_{n,Z}^2$ of F_n converge in probability to v .*

Proof. The distribution function G_n obtained by replacing the mean \bar{X}_n in the definition of F_n by μ_X relates to F_n through

$$F_n(x) = G_n(x + \sqrt{l_n}(\bar{X}_n - \mu_X)).$$

The sequence $\sqrt{l_n}(\bar{X}_n - \mu_X)$ converges in probability to zero, by the assumptions that the sequence $\sqrt{n}(\bar{X}_n - \mu_X)$ converges weakly and that $l_n/n \rightarrow 0$. In view of the monotonicity of the functions F_n and G_n , the claimed convergence of $F_n(x)$ then follows if $G_n(x) \xrightarrow{P} \Phi(x/\sqrt{v})$ for every x . Furthermore, by the triangle inequality the difference between the roots of the second moments of F_n and G_n is bounded by $\sqrt{l_n}|\bar{X}_n - \mu_X|$ and hence tends to zero in probability. Therefore it suffices to prove the claims for G_n instead of F_n .

Fix some x and define $Y_t = 1\{\sqrt{l_n}(Z_{n,t} - \mu_X) \leq x\}$. Then the time series Y_t is strictly stationary and $G_n(x) = \bar{Y}_{n-l_n+1}$. By assumption

$$E\bar{Y}_{n-l_n+1} = P(\sqrt{l_n}(\bar{X}_{l_n} - \mu_X) \leq x) \rightarrow \Phi(x/\sqrt{v}).$$

Because the variable Y_t depends only on the variables X_s with $t \leq s < t + l_n$, the series Y_t is α -mixing with mixing coefficients bounded above by $\alpha(h - l_n)$ for $h > l_n$. Therefore, by (4.2) followed by Lemma 4.12 (with $q = r = \infty$),

$$\text{var } \bar{Y}_{n-l_n+1} \leq \frac{1}{n-l_n+1} \sum_h |\gamma_Y(h)| \leq \frac{4}{n-l_n+1} \left(\sum_{h \geq l_n} \alpha(h-l_n) + l_n \frac{1}{2} \right).$$

This converges to zero as $n \rightarrow \infty$. Thus $G_n(x) = \bar{Y}_{n-l_n+1} \rightarrow \Phi(x/\sqrt{v})$ in probability by Chebyshev's inequality, and the first assertion of the theorem is proved.

By Theorem 3.8 the second moments of a sequence of distributions G_n with $G_n \rightsquigarrow N(0, v)$ tends to v if $\int_{|x| \geq M} x^2 dG_n(x) \rightarrow 0$ as $n \rightarrow \infty$ followed by $M \rightarrow \infty$. We can apply this to the present random distributions G_n , for instance by arguing along almost surely converging subsequences, to conclude that the second moments of the present G_n converge to v if and only if $\int_{|x| \geq M} x^2 dG_n(x) \xrightarrow{P} 0$, as $n \rightarrow \infty$ followed by $M \rightarrow \infty$. Now

$$\begin{aligned} \mathbb{E} \int_{|x| \geq M} x^2 dG_n(x) &= \mathbb{E} \frac{1}{n-l_n+1} \sum_{i=1}^{n-l_n+1} |\sqrt{l_n}(Z_{n,i} - \mu_X)|^2 1\{\sqrt{l_n}|Z_{n,i} - \mu_X| \geq M\} \\ &= \mathbb{E} |\sqrt{l_n}(\bar{X}_{l_n} - \mu_X)|^2 1\{\sqrt{l_n}|\bar{X}_{l_n} - \mu_X| \geq M\}. \end{aligned}$$

By assumption $\sqrt{l_n}(\bar{X}_{l_n} - \mu_X) \rightsquigarrow N(0, v)$, while $\mathbb{E} |\sqrt{l_n}(\bar{X}_{l_n} - \mu_X)|^2 \rightarrow v$ by (4.1) (and Exercise 4.1). Thus we can apply Theorem 3.8 in the other direction to conclude that the right side of the display converges to zero as $n \rightarrow \infty$ followed by $M \rightarrow \infty$. ■

* **5.4 EXERCISE.** Suppose that we center the block means $Z_{n,i}$ at \bar{Z}_{n-l_n+1} instead of \bar{X}_n , and consider the empirical distribution of the variables $\sqrt{l_n}(Z_{n,i} - \bar{Z}_{n-l_n+1})$ and its variance $l_n S_{n,Z}^2$ instead of F_n and $\hat{S}_{n,Z}^2$. Show that the preceding theorem is valid for these quantities provided $l_n/n^{2/3} \rightarrow 0$. [The mean \bar{Z}_{n-l_n+1} of the block means is almost the same as \bar{X}_n . Each X_t with $t \in (l_n, n-l_n+1)$ occurs in exactly l_n block means $Z_{n,i}$, and the X_t with “extreme” indexes occur in between 1 and l_n-1 block means. This shows that $(n-l_n+1)\bar{Z}_{n-l_n+1} = n\bar{X}_n - A_n$, where A_n is a weighted sum of the “extreme” X_t , the weights ranging from $(l_n-1)/l_n$ to $1/l_n$. It follows that $\mathbb{E}|A_n| \leq 2l_n \mathbb{E}|X_1|$.]

The usefulness of the estimator F_n goes beyond its variance. Because it tends to the same limit distribution as the sequence $\sqrt{n}(\bar{X}_n - \mu_X)$, the distribution F_n can serve as an estimator of the distribution of the latter variable. In particular, we could use the quantiles of F_n as estimators of the quantiles of $\sqrt{n}(\bar{X}_n - \mu_X)$ and use these to replace the normal quantiles and $\hat{\sigma}_n$ in the construction of a confidence interval. This gives the interval

$$\left[\bar{X}_n - \frac{F_n^{-1}(0.975)}{\sqrt{n}}, \bar{X}_n - \frac{F_n^{-1}(0.025)}{\sqrt{n}} \right].$$

The preceding theorem shows that this interval has asymptotic confidence level 95% for covering μ_X . Indeed, the theorem shows that $\mathbb{P}(\sqrt{n}(\bar{X}_n - \mu_X) \leq F_n^{-1}(\alpha)) \rightarrow \alpha$, for any $\alpha \in (0, 1)$, which implies that μ_X is contained in the confidence interval with probability tending to 95 %.

The proper choice of the block length l of the method of batched means is crucial: the preceding theorem shows that the estimators will be consistent provided $l_n \rightarrow \infty$ such that $l_n/n \rightarrow 0$. Additional calculations show that, under general conditions, the standard errors of the variance estimators are minimal if l_n is proportional to $n^{1/3}$.[#] Unfortunately, in practice, it is rarely known if these “general conditions” are satisfied, as an optimal block length must depend on the amount of mixing of the time series. Long blocks necessarily have much overlap and hence are positively dependent, which has a negative impact on the variance of the estimators. On the other hand, short blocks cannot properly reflect the dependence structure of the time series, with longer-range dependence needing longer blocks. An optimal block size must balance these conflicting demands.

5.5 EXERCISE. Extend the preceding theorem to the method of batched means.

* 5.1.1 Blockwise Bootstrap

A related method is the *blockwise bootstrap*. Assume that $n = lr$ for simplicity. Given the same blocks $[X_1, \dots, X_l], [X_2, \dots, X_{l+1}], \dots, [X_{n-l+1}, \dots, X_n]$, we choose $r = n/l$ blocks at random with replacement and put the r blocks in a row, in random order, but preserving the order of the X_t within the r blocks. We denote the row of $n = rl$ variables obtained in this way by $X_1^*, X_2^*, \dots, X_n^*$ and let \bar{X}_n^* be their average. The *bootstrap estimator* of the distribution of $\sqrt{n}(\bar{X}_n - \mu_X)$ is by definition the conditional distribution of $\sqrt{n}(\bar{X}_n^* - \bar{X}_n)$ given X_1, \dots, X_n . The corresponding estimator of the variance of $\sqrt{n}(\bar{X}_n - \mu_X)$ is the variance of this conditional distribution.

An equivalent description of the bootstrap procedure is to choose a random sample with replacement from the block averages $Z_{n,1}, \dots, Z_{n,n-l_n+1}$. If this sample is denoted by Z_1^*, \dots, Z_r^* , then the average \bar{X}_n^* is also the average \bar{Z}_r^* . It follows that the bootstrap estimator of the variance of \bar{X}_n is the conditional variance of the mean of a random sample of size r from the block averages given the values $Z_{n,1}, \dots, Z_{n,n-l_n+1}$ of these averages. This is simply $(n/r)S_{n-l_n+1,Z}^2$, as before.

Other aspects of the bootstrap estimators of the distribution, for instance quantiles, are hard to calculate explicitly. In practice we perform computer simulation to obtain an approximation of the bootstrap estimator. By repeating the sampling procedure a large number of times (with the same values of X_1, \dots, X_n), and taking the empirical distribution over the realizations, we can, in principle obtain arbitrary precision.

5.2 Auto Covariances

Replacing a given time series X_t by the centered time series $X_t - \mu_X$ does not change the auto-covariance function. Therefore, for the study of the asymptotic properties of

[#] See Künsch (1989), *Annals of Statistics* 17, p1217–1241.

the sample auto covariance function $\hat{\gamma}_n(h)$, it is not a loss of generality to assume that $\mu_X = 0$. The sample auto-covariance function can be written as

$$\hat{\gamma}_n(h) = \frac{1}{n} \sum_{t=1}^{n-h} X_{t+h} X_t - \bar{X}_n \left(\frac{1}{n} \sum_{t=1}^{n-h} X_t \right) - \left(\frac{1}{n} \sum_{t=1}^{n-h} X_{t+h} \right) \bar{X}_n + \frac{n-h}{n} (\bar{X}_n)^2.$$

Under the conditions of Chapter 4 and the assumption $\mu_X = 0$, the sample mean \bar{X}_n is of the order $O_P(1/\sqrt{n})$ and hence the last term on the right is of the order $O_P(1/n)$. For fixed h the second and third term are almost equivalent to $(\bar{X}_n)^2$ and are also of the order $O_P(1/n)$. Thus, under the assumption that $\mu_X = 0$,

$$\hat{\gamma}_n(h) = \frac{1}{n} \sum_{t=1}^{n-h} X_{t+h} X_t + O_P\left(\frac{1}{n}\right).$$

It follows from this and Slutsky's lemma that the asymptotic behaviour of the sequence $\sqrt{n}(\hat{\gamma}_n(h) - \gamma_X(h))$ depends only on $n^{-1} \sum_{t=1}^{n-h} X_{t+h} X_t$. Here a change of n by $n-h$ (or $n-h$ by n) is asymptotically negligible, so that, for simplicity of notation, we can equivalently study the averages

$$\hat{\gamma}_n^*(h) = \frac{1}{n} \sum_{t=1}^n X_{t+h} X_t.$$

These are unbiased estimators of $E X_{t+h} X_t = \gamma_X(h)$, under the condition that $\mu_X = 0$. Their asymptotic distribution can be derived by applying a central limit theorem to the averages \bar{Y}_n of the variables $Y_t = X_{t+h} X_t$.

If the time series X_t is mixing with mixing coefficients $\alpha(k)$, then the time series Y_t is mixing with mixing coefficients bounded above by $\alpha(k-h)$ for $k > h \geq 0$. Because the conditions for a central limit theorem depend only on the speed at which the mixing coefficients converge to zero, and a shift of the argument by a fixed amount does not change the speed, this means that in most cases the mixing coefficients of the time series X_t and Y_t are equivalent. By the Cauchy-Schwarz inequality the series Y_t has finite moments of order k if the series X_t has finite moments of order $2k$. This means that the mixing central limit theorems for the sample mean apply without further difficulties to proving the asymptotic normality of the sample auto-covariance function. The asymptotic variance takes the form $\sum_g \gamma_Y(g)$ and in general depends on fourth order moments of the type $E X_{t+g+h} X_{t+g} X_{t+h} X_t$ as well as on the auto-covariance function of the series X_t . In its generality, its precise form is not of much interest.

5.6 Theorem. *If X_t is a strictly stationary, mixing time series with α -mixing coefficients such that $\int_0^1 \alpha^{-1}(u) F_{|X_h X_0|}^{-1}(1-u)^2 du < \infty$, then the sequence $\sqrt{n}(\hat{\gamma}_n(h) - \gamma_X(h))$ converges in distribution to a normal distribution.*

Proof. It can be seen that the mixing coefficients of $Y_t = X_{t+h} X_t$ satisfy $\alpha^Y(g) \leq \alpha(g-h)$, for $g \geq h$. This implies that $(\alpha^Y)^{-1}(u) = \sum_g 1_{u < \alpha^Y(g)} \leq h/2 + \alpha^{-1}(u)$. Therefore the theorem follows from Theorem 4.7 applied to \bar{Y}_n . ■

Another approach to central limit theorems is special to linear processes, of the form (4.4), for a sequence $\dots, Z_{-1}, Z_0, Z_1, Z_2, \dots$ of independent and identically distributed variables with $EZ_t = 0$, and constants ψ_j satisfying $\sum_j |\psi_j| < \infty$. The sample auto-covariance function of a linear process is also asymptotically normal, but the proof of this requires additional work. This work is worth while mainly because the limit variance takes a simple form in this case.

Under (4.4) with $\mu = 0$, the auto-covariance function of the series $Y_t = X_{t+h}X_t$ can be calculated as

$$\begin{aligned}\gamma_Y(g) &= \text{cov}(X_{t+g+h}X_{t+g}, X_{t+h}X_t) \\ &= \sum_i \sum_j \sum_k \sum_l \psi_{t-i} \psi_{t+h-j} \psi_{t+g-k} \psi_{t+g+h-l} \text{cov}(Z_i Z_j, Z_k Z_l).\end{aligned}$$

Here $\text{cov}(Z_i Z_j, Z_k Z_l)$ is zero whenever one of the indices i, j, k, l occurs only once. For instance $EZ_1 Z_2 Z_{10} Z_2 = EZ_1 EZ_2^2 EZ_{10} = 0$. It also vanishes if $i = j \neq k = l$, by independence of $Z_i Z_j$ and $Z_k Z_l$. The covariance is nonzero only if all four indices are the same, or if the indices occur in the pairs $i = k \neq j = l$ or $i = l \neq j = k$. Thus the preceding display can be rewritten as

$$\begin{aligned}& \text{cov}(Z_1^2, Z_1^2) \sum_i \psi_{t-i} \psi_{t+h-i} \psi_{t+g-i} \psi_{t+g+h-i} \\ & + \text{cov}(Z_1 Z_2, Z_1 Z_2) \sum_{i \neq j} \psi_{t-i} \psi_{t+h-j} \psi_{t+g-i} \psi_{t+g+h-j} \\ & + \text{cov}(Z_1 Z_2, Z_2 Z_1) \sum_{i \neq j} \psi_{t-i} \psi_{t+h-j} \psi_{t+g-j} \psi_{t+g+h-i} \\ & = (EZ_1^4 - 3(EZ_1^2)^2) \sum_i \psi_i \psi_{i+h} \psi_{i+g} \psi_{i+g+h} + \gamma_X(g)^2 + \gamma_X(g+h)\gamma_X(g-h).\end{aligned}$$

In the last step we use Lemma 1.29(iii) twice, after first adding the diagonal terms $i = j$ to the double sums. Since $\text{cov}(Z_1 Z_2, Z_1 Z_2) = (EZ_1^2)^2$, these diagonal terms account for -2 of the -3 times the sum in the first term. The variance of $\sqrt{n}\hat{\gamma}_n^*(h) = \sqrt{n}\bar{Y}_n$ converges to the sum over g of this expression. With $\kappa_4(Z) = EZ_1^4/(EZ_1^2)^2 - 3$, the *fourth cumulant* (equal to the *kurtosis* minus 3 divided by the square variance) of Z_t , this sum can be written as

$$V_{h,h} = \kappa_4(Z)\gamma_X(h)^2 + \sum_g \gamma_X(g)^2 + \sum_g \gamma_X(g+h)\gamma_X(g-h).$$

5.7 Theorem. *If (4.4) holds for an i.i.d. sequence Z_t with mean zero and $EZ_t^4 < \infty$ and numbers ψ_j with $\sum_j |\psi_j| < \infty$, then $\sqrt{n}(\hat{\gamma}_n(h) - \gamma_X(h)) \rightsquigarrow N(0, V_{h,h})$.*

Proof. As explained in the discussion preceding the statement of the theorem, it suffices to show that the sequence $\sqrt{n}(\hat{\gamma}_n^*(h) - \gamma_X(h))$ has the given asymptotic distribution in the case that $\mu = 0$. Define $Y_t = X_{t+h}X_t$ and, for fixed $m \in \mathbb{N}$,

$$Y_t^m = \sum_{|i| \leq m} \psi_i Z_{t+h-i} \sum_{|j| \leq m} \psi_j Z_{t-j} =: X_{t+h}^m X_t^m.$$

The time series Y_t^m is $(2m + h)$ -dependent and strictly stationary. By Theorem 4.4 the sequence $\sqrt{n}(\bar{Y}_n^m - E\bar{Y}_n^m)$ is asymptotically normal with mean zero and variance

$$V_{h,h}^m := \sum_g \gamma_{Y_m}(g) = \kappa_4(Z) \gamma_{X^m}(h)^2 + \sum_g \gamma_{X^m}(g)^2 + \sum_g \gamma_{X^m}(g+h) \gamma_{X^m}(g-h),$$

where the second equality follows from the calculations preceding the theorem. For every g , as $m \rightarrow \infty$,

$$\gamma_{X^m}(g) = EZ_1^2 \sum_{j: |j| \leq m, |j+g| \leq m} \psi_j \psi_{j+g} \rightarrow EZ_1^2 \sum_j \psi_j \psi_{j+g} = \gamma_X(g).$$

Furthermore, the numbers on the left are bounded above by $EZ_1^2 \sum_j |\psi_j \psi_{j+g}|$, and

$$\sum_g \left(\sum_j |\psi_j \psi_{j+g}| \right)^2 = \sum_g \sum_i \sum_j |\psi_i \psi_j \psi_{i+g} \psi_{j+g}| \leq \sup_j |\psi_j| \left(\sum_j |\psi_j| \right)^3 < \infty.$$

Therefore, by the dominated convergence theorem $\sum_g \gamma_{X^m}(g)^2 \rightarrow \sum_g \gamma_X(g)^2$ as $m \rightarrow \infty$. By a similar argument, we obtain the corresponding property for the third term in the expression defining $V_{h,h}^m$, whence $V_{h,h}^m \rightarrow V_{h,h}$ as $m \rightarrow \infty$.

We conclude by Lemma 3.10 that there exists a sequence $m_n \rightarrow \infty$ such that $\sqrt{n}(\bar{Y}_n^{m_n} - E\bar{Y}_n^{m_n}) \rightsquigarrow N(0, V_{h,h})$. The proof of the theorem is complete once we also have shown that the difference between the sequences $\sqrt{n}(\bar{Y}_n - E\bar{Y}_n)$ and $\sqrt{n}(\bar{Y}_n^{m_n} - E\bar{Y}_n^{m_n})$ converges to zero in probability.

Both sequences are centered at mean zero. In view of Chebyshev's inequality it suffices to show that $n \text{var}(\bar{Y}_n - \bar{Y}_n^{m_n}) \rightarrow 0$. We can write

$$Y_t - Y_t^m = X_{t+h}X_t - X_{t+h}^mX_t^m = \sum_i \sum_j \psi_{t-i, t+h-j}^m Z_i Z_j,$$

where $\psi_{i,j}^m = 0$ if $|i| \leq m$ and $|j| \leq m$ and $\psi_i \psi_j$ otherwise. The variables $\bar{Y}_n - \bar{Y}_n^m$ are the averages of these double sums and hence \sqrt{n} times their variance can be found as

$$\begin{aligned} & \sum_{g=-n}^n \left(\frac{n-|g|}{n} \right) \gamma_{Y-Y^m}(g) \\ &= \sum_{g=-n}^n \left(\frac{n-|g|}{n} \right) \sum_i \sum_j \sum_k \sum_l \psi_{t-i, t+h-j}^m \psi_{t+g-k, t+g+h-l}^m \text{cov}(Z_i Z_j, Z_k Z_l). \end{aligned}$$

Most terms in this five-fold sum are zero and by similar arguments as before the whole expression can be bounded in absolute value by

$$\begin{aligned} & \text{cov}(Z_1^2, Z_1^2) \sum_g \sum_i |\psi_{i, i+h}^m \psi_{g, g+h}^m| + (EZ_1^2)^2 \sum_g \sum_i \sum_j |\psi_{i,j}^m \psi_{i+g, j+g}^m| \\ & \quad + (EZ_1^2)^2 \sum_g \sum_i \sum_j |\psi_{i, j+h}^m \psi_{j+g, i+g+h}^m|. \end{aligned}$$

We have that $\psi_{i,j}^m \rightarrow 0$ as $m \rightarrow \infty$ for every fixed (i, j) , $|\psi_{i,j}^m| \leq |\psi_i \psi_j|$, and $\sup_i |\psi_i| \leq \sum_i |\psi_i| < \infty$. By the dominated convergence theorem the double and triple sums converge to zero as well. ■

By similar arguments we can also prove the joint asymptotic normality of the sample auto-covariances for a number of lags h simultaneously. By the Cramér-Wold device a sequence of k -dimensional random vectors X_n converges in distribution to a random vector X if and only if $a^T X_n \rightsquigarrow a^T X$ for every $a \in \mathbb{R}^k$. A linear combination of sample auto-covariances can be written as an average, as before. These averages can be shown to be asymptotically normal by the same methods, with only the notation becoming more complex.

5.8 Theorem. *Under the conditions of either Theorem 5.6 or 5.7, for every $h \in \mathbb{N}$ and some $(h+1) \times (h+1)$ -matrix V ,*

$$\sqrt{n} \left(\begin{pmatrix} \hat{\gamma}_n(0) \\ \vdots \\ \hat{\gamma}_n(h) \end{pmatrix} - \begin{pmatrix} \gamma_X(0) \\ \vdots \\ \gamma_X(h) \end{pmatrix} \right) \rightsquigarrow N_{h+1}(0, V).$$

For a linear process X_t (as in (4.4)) the matrix V has (g, h) -element

$$V_{g,h} = \kappa_4(Z) \gamma_X(g) \gamma_X(h) + \sum_k \gamma_X(k+g) \gamma_X(k+h) + \sum_k \gamma_X(k-g) \gamma_X(k+h).$$

5.3 Auto Correlations

The asymptotic distribution of the auto-correlations $\hat{\rho}_n(h)$ can be obtained from the asymptotic distribution of the auto-covariance function by the Delta-method (Theorem 3.15). We can write

$$\hat{\rho}_n(h) = \frac{\hat{\gamma}_n(h)}{\hat{\gamma}_n(0)} = \phi(\hat{\gamma}_n(0), \hat{\gamma}_n(h)),$$

for ϕ the function given by $\phi(u, v) = v/u$. This function has gradient $(-v/u^2, 1/u)$. By the Delta-method,

$$\begin{aligned} \sqrt{n}(\hat{\rho}_n(h) - \rho_X(h)) &= -\frac{\gamma_X(h)}{\gamma_X(0)^2} \sqrt{n}(\hat{\gamma}_n(0) - \gamma_X(0)) \\ &\quad + \frac{1}{\gamma_X(0)} \sqrt{n}(\hat{\gamma}_n(h) - \gamma_X(h)) + o_P(1). \end{aligned}$$

The limit distribution of the right side is the distribution of the random variable $-\gamma_X(h)/\gamma_X(0)^2 Y_0 + 1/\gamma_X(0) Y_h$, for Y_0 and Y_h the first and last coordinate of a random vector Y with the $N_{h+1}(0, V)$ -distribution given in Theorem 5.8. The joint limit

distribution of a vector of auto-correlations is the joint distribution of the corresponding linear combinations of the Y_h . By linearity this is a Gaussian distribution; its mean is zero and its covariance matrix can be expressed in the matrix V by linear algebra.

5.9 Theorem. *Under the conditions of either Theorem 5.6 or 5.7, for every $h \in \mathbb{N}$ and some $h \times h$ -matrix W ,*

$$\sqrt{n} \left(\begin{pmatrix} \hat{\rho}_n(1) \\ \vdots \\ \hat{\rho}_n(h) \end{pmatrix} - \begin{pmatrix} \rho_X(1) \\ \vdots \\ \rho_X(h) \end{pmatrix} \right) \rightsquigarrow N_h(0, W),$$

For a linear process X_t the matrix W has (g, h) -element

$$W_{g,h} = \sum_k \left[\rho_X(k+g)\rho_X(k+h) + \rho_X(k-g)\rho_X(k+h) + 2\rho_X(g)\rho_X(h)\rho_X(k)^2 \right. \\ \left. - 2\rho_X(g)\rho_X(k)\rho_X(k+h) - 2\rho_X(h)\rho_X(k)\rho_X(k+g) \right].$$

The expression for the asymptotic covariance matrix W of the auto-correlation coefficients in the case of a linear process is known as *Bartlett's formula*. An interesting fact is that W depends on the auto-correlation function ρ_X only, although the asymptotic covariance matrix V of the sample auto-covariance coefficients depends also on the second and fourth moments of Z_1 . We discuss two interesting examples of this formula.

5.10 Example (Iid sequence). For $\psi_0 = 1$ and $\psi_j = 0$ for $j \neq 0$, the linear process X_t given by (4.4) is equal to the i.i.d. sequence $\mu + Z_t$. Then $\rho_X(h) = 0$ for every $h \neq 0$ and the matrix W given by Bartlett's formula can be seen to reduce to the identity matrix. This means that for large n the sample auto-correlations $\hat{\rho}_n(1), \dots, \hat{\rho}_n(h)$ are approximately independent normal variables with mean zero and variance $1/n$.

This can be used to test whether a given sequence of random variables is independent. If the variables are independent and identically distributed, then approximately 95 % of the computed auto-correlations should be in the interval $[-1.96/\sqrt{n}, 1.96/\sqrt{n}]$. This is often verified graphically, from a plot of the auto-correlation function, on which the given interval is indicated by two horizontal lines. Note that, just as we should expect that 95 % of the sample auto-correlations are inside the two bands in the plot, we should also expect that 5 % of them are not! A more formal test would be to compare the sum of the squared sample auto-correlations to the appropriate chisquare table. The *Ljung-Box* statistic is defined by

$$\sum_{h=1}^k \frac{n(n+2)}{n-h} \hat{\rho}_n(h)^2.$$

By the preceding theorem, for fixed k , this sequence of statistics tends to the χ^2 -distribution with k degrees of freedom, as $n \rightarrow \infty$. (The coefficients $n(n+2)/(n-h)$ are motivated by a calculation of moments for finite n and are thought to improve the chisquare approximation, but are asymptotically equivalent to $(\sqrt{n})^2$.)

The more auto-correlations we use in a procedure of this type, the more information we extract from the data and hence the better the result. However, the tests are based on the asymptotic distribution of the sample auto-correlations and this was derived under the assumption that the lag h is fixed and $n \rightarrow \infty$. We should expect that the convergence to normality is slower for sample auto-correlations $\hat{\rho}_n(h)$ of larger lags h , since there are fewer terms in the sums defining them. Thus in practice we should not use sample auto-correlations of lags that are large relative to n .

Clearly the Ljung-Box test does not really test independence, but only zero auto-correlation. If the X_t are independent, then so are any measurable transformations $\psi(X_t)$. In practice one might therefore apply the test also to squares X_t^2 , logarithms $\log|X_t|$, etc. \square

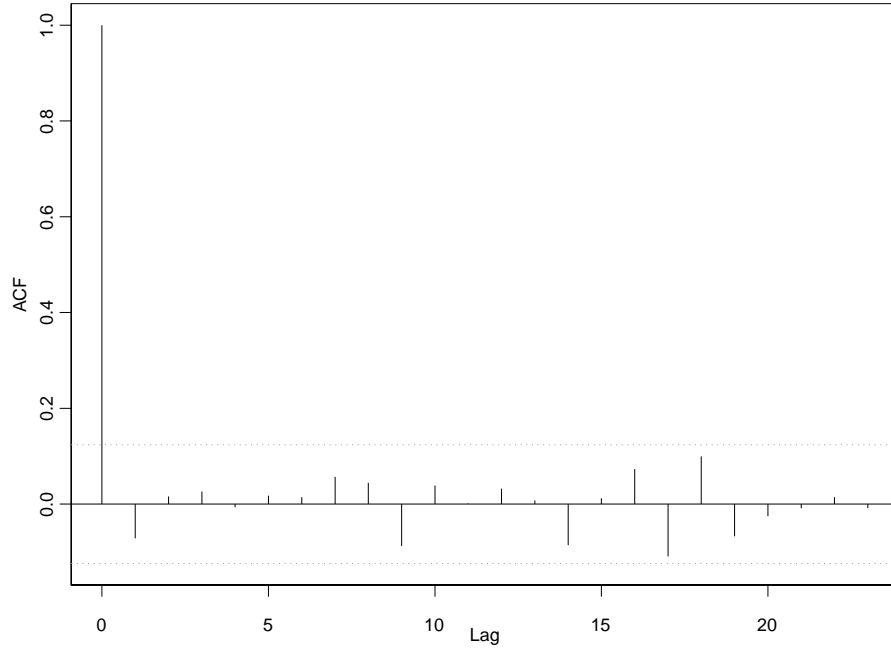

Figure 5.2. Realization of the sample auto-correlation function of a Gaussian white noise series of length 250. The horizontal bands are drawn at heights $\pm 1/\sqrt{250}$.

- * **5.11 Example (Moving average).** For a moving average $X_t = Z_t + \theta_1 Z_{t-1} + \cdots + \theta_q Z_{t-q}$ of order q , the auto-correlations $\rho_X(h)$ of lags $h > q$ vanish. By the preceding theorem the sequence $\sqrt{n}\hat{\rho}_n(h)$ converges for $h > q$ in distribution to a normal distribution with variance

$$W_{h,h} = \sum_k \rho_X(k)^2 = 1 + 2\rho_X(1)^2 + \cdots + 2\rho_X(q)^2, \quad h > q.$$

This can be used to test whether a moving average of a given order q is an appropriate model for a given observed time series. A plot of the auto-correlation function shows

nonzero auto-correlations for lags $1, \dots, q$, and zero values for lags $h > q$. In practice we plot the sample auto-correlation function. Just as in the preceding example, we should expect that some sample auto-correlations of lags $h > q$ are significantly different from zero, due to estimation errors. The asymptotic variances $W_{h,h}$ are bigger than 1 and hence we should take the confidence bands a bit wider than the intervals $[-1.96/\sqrt{n}, 1.96/\sqrt{n}]$ as in the preceding example. A proper interpretation is more complicated, because the sample auto-correlations are not asymptotically independent. \square

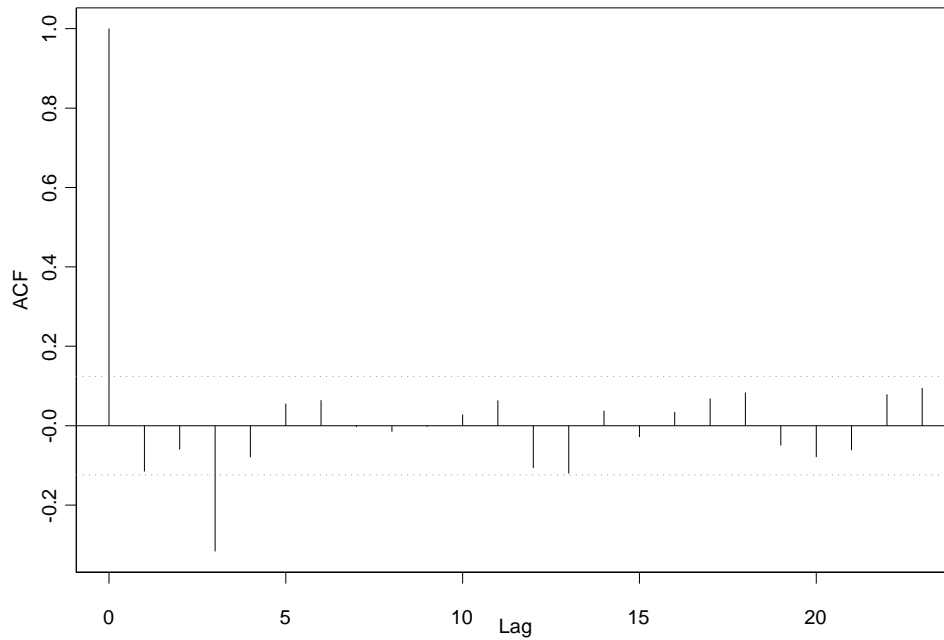

Figure 5.3. Realization ($n = 250$) of the sample auto-correlation function of the moving average process $X_t = 0.5Z_t + 0.2Z_{t-1} + 0.5Z_{t-2}$ for a Gaussian white noise series Z_t . The horizontal bands are drawn at heights $\pm 1/\sqrt{250}$.

5.12 EXERCISE. Verify the formula for $W_{h,h}$ in the preceding example.

5.13 EXERCISE. Find $W_{1,1}$ as a function of θ for the process $X_t = Z_t + \theta Z_{t-1}$.

5.14 EXERCISE. Verify Bartlett's formula.

5.4 Partial Auto Correlations

By Lemma 2.36 and the prediction equations the partial auto-correlation $\alpha_X(h)$ is the solution ϕ_h of the system of equations

$$\begin{pmatrix} \gamma_X(0) & \gamma_X(1) & \cdots & \gamma_X(h-1) \\ \vdots & \vdots & & \vdots \\ \gamma_X(h-1) & \gamma_X(h-2) & \cdots & \gamma_X(0) \end{pmatrix} \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_h \end{pmatrix} = \begin{pmatrix} \gamma_X(1) \\ \vdots \\ \gamma_X(h) \end{pmatrix}.$$

A nonparametric estimator $\hat{\alpha}_n(h)$ of $\alpha_X(h)$ is obtained by replacing the auto-covariance function in this linear system by the sample auto-covariance function $\hat{\gamma}_n$. This yields estimators $\hat{\phi}_1, \dots, \hat{\phi}_h$ of the prediction coefficients satisfying

$$\begin{pmatrix} \hat{\gamma}_n(0) & \hat{\gamma}_n(1) & \cdots & \hat{\gamma}_n(h-1) \\ \vdots & \vdots & & \vdots \\ \hat{\gamma}_n(h-1) & \hat{\gamma}_n(h-2) & \cdots & \hat{\gamma}_n(0) \end{pmatrix} \begin{pmatrix} \hat{\phi}_1 \\ \vdots \\ \hat{\phi}_h \end{pmatrix} = \begin{pmatrix} \hat{\gamma}_n(1) \\ \vdots \\ \hat{\gamma}_n(h) \end{pmatrix}.$$

We define a nonparametric estimator for $\alpha_X(h)$ by $\hat{\alpha}_n(h) = \hat{\phi}_h$. The function $h \mapsto \hat{\alpha}_n(h)$ is called the *sample partial auto-covariance function*.

If we write these two systems of equations as $\Gamma\phi = \gamma$ and $\hat{\Gamma}\hat{\phi} = \hat{\gamma}$, respectively, then we obtain that

$$\hat{\phi} - \phi = \hat{\Gamma}^{-1}\hat{\gamma} - \Gamma^{-1}\gamma = \hat{\Gamma}^{-1}(\hat{\gamma} - \gamma) - \hat{\Gamma}^{-1}(\hat{\Gamma} - \Gamma)\Gamma^{-1}\gamma.$$

The sequences $\sqrt{n}(\hat{\gamma} - \gamma)$ and $\sqrt{n}(\hat{\Gamma} - \Gamma)$ are jointly asymptotically normal by Theorem 5.8. With the help of Slutsky's lemma and the continuous mapping theorem we readily obtain the asymptotic normality of the sequence $\sqrt{n}(\hat{\phi} - \phi)$ and hence of the sequence $\sqrt{n}(\hat{\alpha}_n(h) - \alpha_X(h))$. The asymptotic covariance matrix appears to be complicated, in general; we shall not derive it, except in the special case of the following example.

5.15 Example (Autoregression). For the stationary solution to $X_t = \phi X_{t-1} + Z_t$ and $|\phi| < 1$, the partial auto-correlations of lags $h \geq 2$ vanish, by Example 2.37. In Section 11.1.2 it is shown that the sequence $\sqrt{n}\hat{\alpha}_n(h)$ is asymptotically standard normally distributed, for every $h \geq 2$.

This result extends to the “causal” solution of the p th order auto-regressive scheme $X_t = \phi_1 X_{t-1} + \cdots + \phi_p X_{t-p} + Z_t$ and the auto-correlations of lags $h > p$. (The meaning of “causal” is explained in Chapter 8.) This property can be used to find an appropriate order p when fitting an auto-regressive model to a given time series. The order is chosen such that “most” of the sample auto-correlations of lags bigger than p are within the band $[-1.96/\sqrt{n}, 1.96/\sqrt{n}]$. A proper interpretation of “most” requires that the dependence of the $\hat{\alpha}_n(h)$ is taken into consideration. \square

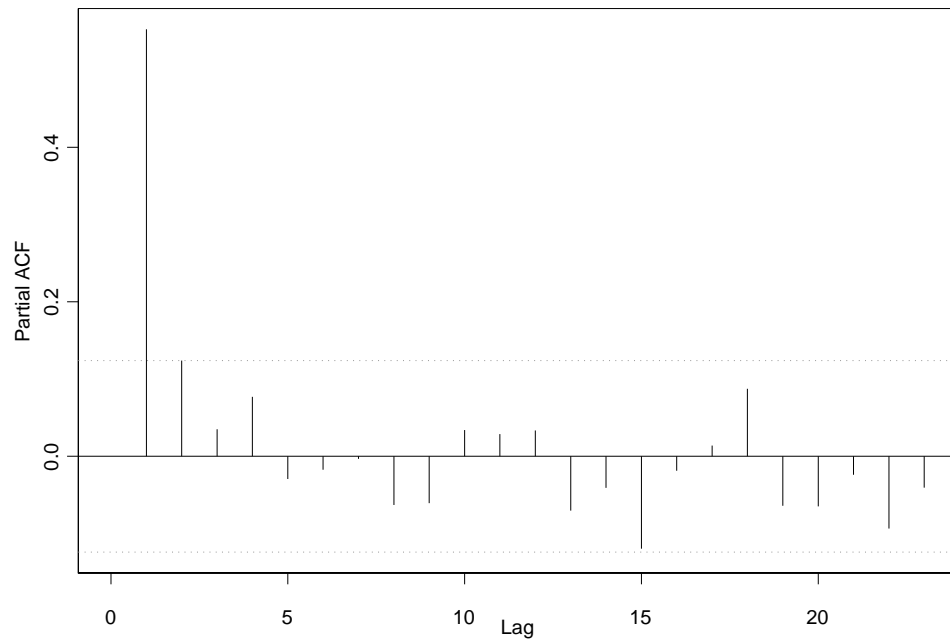

Figure 5.4. Realization ($n = 250$) of the partial auto-correlation function of the stationary solution to $X_t = 0.5X_{t-1} + 0.2X_{t-1} + Z_t$ for a Gaussian white noise series.

6

Spectral Theory

Let X_t be a stationary, possibly complex, time series with auto-covariance function γ_X . If the series $\sum_h |\gamma_X(h)|$ is convergent, then the series

$$(6.1) \quad f_X(\lambda) = \frac{1}{2\pi} \sum_{h \in \mathbb{Z}} \gamma_X(h) e^{-ih\lambda},$$

is absolutely convergent, uniformly in $\lambda \in \mathbb{R}$. This function is called the *spectral density* of the time series X_t . Because it is periodic with period 2π it suffices to consider it on an interval of length 2π , which we shall take to be $(-\pi, \pi]$. In the present context the values λ in this interval are often referred to as *frequencies*, for reasons that will become clear. By the uniform convergence, we can exchange the order of integral and sum when computing $\int_{-\pi}^{\pi} e^{ih\lambda} f_X(\lambda) d\lambda$ and we find that, for every $h \in \mathbb{Z}$,

$$(6.2) \quad \gamma_X(h) = \int_{-\pi}^{\pi} e^{ih\lambda} f_X(\lambda) d\lambda.$$

Thus the spectral density f_X determines the auto-covariance function, just as the auto-covariance function determines the spectral density.

6.1 EXERCISE. Verify the *orthonormality* of the *trigonometric basis*: $\int_{-\pi}^{\pi} e^{ih\lambda} d\lambda = 0$ for integers $h \neq 0$ and $\int_{-\pi}^{\pi} e^{ih\lambda} d\lambda = 2\pi$ for $h = 0$. Use this to prove the *inversion formula* (6.2), under the condition that $\sum_h |\gamma_X(h)| < \infty$.

In mathematical analysis the series f_X is called a *Fourier series* and the numbers $\gamma_X(h)$ are called the *Fourier coefficients* of f_X . (The factor $1/(2\pi)$ is sometimes omitted or replaced by another number, and the Fourier series is often defined as $f_X(-\lambda)$ rather than $f_X(\lambda)$, but this is inessential.) A central result in Fourier analysis is that the series in (6.1) converges in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$, and (6.2) is true, if and only if $\sum_h |\gamma_X(h)|^2 < \infty$. (See Lemma 6.3 below; the latter condition is weaker than the absolute summability of the autocovariances.) Furthermore, the converse of this statement is also true: if complex numbers $\gamma_X(h)$ are defined by (6.2) from a given function $f_X \in L_2((-\pi, \pi], \mathcal{B}, \lambda)$, then the

latter function can be recovered from (6.1), where the convergence is in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$. This involves the *completeness* of the trigonometric basis, consisting of the functions $\lambda \mapsto (2\pi)^{-1/2} e^{-ih\lambda}$, for $h \in \mathbb{Z}$.

6.1 Spectral Measures

The requirement that the series $\sum_h |\gamma_X(h)|$ or $\sum_h |\gamma_X(h)|^2$ are convergent means roughly that $\gamma_X(h) \rightarrow 0$ as $h \rightarrow \pm\infty$ at a “sufficiently fast” rate. In statistical terms it means that variables X_t that are widely separated in time must be approximately uncorrelated. This is not true for every time series, and consequently not every time series possesses a spectral density. However, every stationary time series does have a “spectral measure”, by the following theorem.

6.2 Theorem (Herglotz). *For every stationary time series X_t there exists a unique finite measure F_X on $(-\pi, \pi]$ such that*

$$\gamma_X(h) = \int_{(-\pi, \pi]} e^{ih\lambda} dF_X(\lambda), \quad h \in \mathbb{Z}.$$

Proof. Define F_n as the measure on $[-\pi, \pi]$ with Lebesgue density equal to

$$f_n(\lambda) = \frac{1}{2\pi} \sum_{h=-n}^n \gamma_X(h) \left(1 - \frac{|h|}{n}\right) e^{-ih\lambda}.$$

It is not immediately clear that this is a real-valued, nonnegative function, but this follows from the fact that

$$0 \leq \frac{1}{2\pi n} \operatorname{var} \left(\sum_{t=1}^n X_t e^{-it\lambda} \right) = \frac{1}{2\pi n} \sum_{s=1}^n \sum_{t=1}^n \operatorname{cov}(X_s, X_t) e^{i(t-s)\lambda} = f_n(\lambda).$$

It is clear from the definition of f_n that the numbers $\gamma_X(h)(1 - |h|/n)$ are the Fourier coefficients of f_n for $|h| \leq n$ (and the remaining Fourier coefficients of f_n are zero). Thus, by the inversion formula,

$$\gamma_X(h) \left(1 - \frac{|h|}{n}\right) = \int_{-\pi}^{\pi} e^{ih\lambda} f_n(\lambda) d\lambda = \int_{-\pi}^{\pi} e^{ih\lambda} dF_n(\lambda), \quad |h| \leq n.$$

Setting $h = 0$ in this equation, we see that $F_n[-\pi, \pi] = \gamma_X(0)$ for every n . Thus, apart from multiplication by the constant $\gamma_X(0)$, the F_n are probability distributions. Because the interval $[-\pi, \pi]$ is compact, the sequence F_n is uniformly tight. By Prohorov's theorem there exists a subsequence $F_{n'}$ that converges weakly to a distribution F on $[-\pi, \pi]$ of the same total mass. Because $\lambda \mapsto e^{ih\lambda}$ is a continuous function, it follows by the portmanteau lemma that

$$\int_{[-\pi, \pi]} e^{ih\lambda} dF(\lambda) = \lim_{n' \rightarrow \infty} \int_{[-\pi, \pi]} e^{ih\lambda} dF_{n'}(\lambda) = \gamma_X(h),$$

by the preceding display. If F puts a positive mass at $-\pi$, we can move this to the point π without affecting this identity, since $e^{-ih\pi} = e^{ih\pi}$ for every $h \in \mathbb{Z}$. The resulting F satisfies the requirements for F_X .

That this F is unique can be proved using the fact that the linear span of the functions $\lambda \mapsto e^{ih\lambda}$ is uniformly dense in the set of continuous, periodic functions.[†] This allows to extend equality $\int k dF = \int k dG$, for two measures F and G and every function k of the form $\lambda \mapsto e^{i\lambda h}$ to equality for any continuous, periodic function k . Using the monotone and/or dominated convergence theorems, we can further extend this to any bounded measurable function k . This implies that $F = G$. ■

The measure F_X is called the *spectral measure* of the time series X_t . If the spectral measure F_X admits a density f_X relative to the Lebesgue measure, then the latter is called the *spectral density*. A sufficient condition for this is that the square summability of the square autocovariances. Then the spectral density is the Fourier series (6.1), with Fourier coefficients $\gamma_X(h)$.

6.3 Lemma. *If $\sum_h |\gamma_X(h)|^2 < \infty$, then the series (6.1) converges in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$, and defines a density of F_X relative to Lebesgue measure.*

Proof. The orthonormality of the trigonometric basis shows that, for any $m \leq n$,

$$\begin{aligned} \int_{-\pi}^{\pi} \left| \sum_{m \leq |h| \leq n} \gamma_X(h) e^{-ih\lambda} \right|^2 d\lambda &= \sum_{m \leq |g| \leq n} \sum_{m \leq |h| \leq n} \gamma_X(h) \overline{\gamma_X(g)} \int_{-\pi}^{\pi} e^{i(h-g)\lambda} d\lambda \\ &= 2\pi \sum_{m \leq |h| \leq n} |\gamma_X(h)|^2. \end{aligned}$$

Thus the convergence of the series $\sum |\gamma_X(h)|^2$ is equivalent to the convergence of the series (6.1) in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$.

Next the continuity of the inner product in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$ allows exchanging the order of integration and summation in $\int_{-\pi}^{\pi} e^{ig\lambda} \sum_h \gamma_X(h) e^{-ih\lambda} d\lambda$. Then (6.2) follows from the orthonormality of the trigonometric basis (as in Exercise 6.1). ■

6.4 EXERCISE. Show that the spectral density of a real-valued time series with $\sum_h |\gamma_X(h)| < \infty$ is symmetric about zero.

* **6.5 EXERCISE.** Show that the spectral measure of a real-valued time series is symmetric about zero, apart from a possible point mass at π . [Hint: Use the uniqueness of a spectral measure.]

6.6 Example (White noise). The covariance function of a white noise sequence X_t is 0 for $h \neq 0$. Thus the Fourier series defining the spectral density has only one term and reduces to

$$f_X(\lambda) = \frac{1}{2\pi} \gamma_X(0).$$

[†] See *Rudin*, Theorem 4.25. In fact, by Fejér's theorem, the Césaro sums of the Fourier series of a continuous, periodic function converge uniformly to the function.

The spectral measure is the uniform measure with total mass $\gamma_X(0)$. Hence “a white noise series contains all possible frequencies in an equal amount”. \square

6.7 Example (Deterministic trigonometric series). Let $X_t = A \cos(\lambda t) + B \sin(\lambda t)$ for mean-zero, uncorrelated variables A and B of variance σ^2 , and $\lambda \in (0, \pi)$. By Example 1.5 the covariance function is given by

$$\gamma_X(h) = \sigma^2 \cos(h\lambda) = \sigma^2 \frac{1}{2}(e^{i\lambda h} + e^{-i\lambda h}).$$

It follows that the spectral measure F_X is the discrete 2-point measure with $F_X\{\lambda\} = F_X\{-\lambda\} = \sigma^2/2$.

Because the time series is real, the point mass at $-\lambda$ does not really count: because the spectral measure of a real time series is symmetric, the point $-\lambda$ must be there because λ is there. The form of the spectral measure and the fact that the time series in this example is a trigonometric series of frequency λ , are good motivation for referring to the values λ as “frequencies”. \square

6.8 EXERCISE.

- (i) Show that the spectral measure of the sum $X_t + Y_t$ of two uncorrelated time series is the sum of the spectral measures of X_t and Y_t .
- (ii) Construct a time series with spectral measure equal to a symmetric discrete measure on the points $\pm\lambda_1, \pm\lambda_2, \dots, \pm\lambda_k$ with $0 < \lambda_1 < \dots < \lambda_k < \pi$.
- (iii) Construct a time series with spectral measure the 1-point measure with $F_X\{0\} = \sigma^2$.
- (iv) Same question, but now with $F_X\{\pi\} = \sigma^2$.

* **6.9 EXERCISE.** Show that every finite measure on $(-\pi, \pi]$ is the spectral measure of some stationary time series.

The spectrum of a time series is an important theoretical concept, but it is also an important practical tool to gain insight in periodicities in the data. Inference using the spectrum is called *spectral analysis* or analysis in the *frequency domain* as opposed to “ordinary” analysis, which is in the *time domain*. It depends on the subject field whether a spectral analysis is useful. If there are periodicities present in a time series, then a spectral analysis will reveal these. However, in general we should not have too great expectations of the insight offered by the spectrum. For instance, the interpretation of the spectrum of economic time series may be complicated, or even unclear, due to the fact that all possible frequencies are present to some nontrivial extent.

The idea of a spectral analysis is to view the consecutive values

$$\dots, X_{-1}, X_0, X_1, X_2, \dots$$

of a time series as a random function $X: \mathbb{Z} \subset \mathbb{R} \rightarrow \mathbb{R}$, and to write this as a weighted sum (or integral) of trigonometric functions $t \mapsto \cos \lambda t$ or $t \mapsto \sin \lambda t$ of different frequencies λ . In simple cases finitely many frequencies suffice, whereas in other situations all frequencies $\lambda \in (-\pi, \pi]$ are needed to give a full description, and the “weighted sum” becomes an integral. Examples TrigonometricSeries6.7 and 6.6 provide two extremes:

a deterministic trigonometric series incorporates a single frequency, and a white noise series has all frequencies in equal amounts. In general the spectral measure gives the weights of the different frequencies in the sum.

We shall derive the *spectral decomposition*, the theoretical basis for this interpretation, in Section 6.4. Another method to gain insight in the interpretation of a spectrum is to consider its transformation under filtering. The term “filtering” stems from the field of signal processing, where a filter takes the form of an physical device that filters out certain frequencies from a given electric current. For us, a (linear) filter will remain an infinite moving average as defined in Chapter 1.

6.10 Definition (Transfer function). *The transfer function (or frequency response function for a filter with filter coefficients ψ_j is the function $\psi: (-\pi, \pi] \rightarrow \mathbb{C}$ given by*

$$\psi(\lambda) = \sum_{j=-\infty}^{\infty} \psi_j e^{-ij\lambda}.$$

The gain is the modulus of the transfer function.

6.11 Theorem. *Let X_t be a stationary time series with spectral measure F_X and let $\sum_j |\psi_j| < \infty$. Then $Y_t = \sum_j \psi_j X_{t-j}$ has spectral measure F_Y given by, with ψ the transfer function,*

$$dF_Y(\lambda) = |\psi(\lambda)|^2 dF_X(\lambda).$$

Proof. According to Lemma 1.29(iii) (if necessary extended to complex-valued filters), the series Y_t is stationary with auto-covariance function

$$\gamma_Y(h) = \sum_k \sum_l \psi_k \bar{\psi}_l \gamma_X(h - k + l) = \sum_k \sum_l \psi_k \bar{\psi}_l \int e^{i(h-k+l)\lambda} dF_X(\lambda).$$

By the dominated convergence theorem we are allowed to change the order of (double) summation and integration. Next we can rewrite the right side as $\int |\psi(\lambda)|^2 e^{ih\lambda} dF_X(\lambda)$. This proves the theorem, in view of Theorem 6.2 and the uniqueness of the spectral measure. ■

6.12 Example (Moving average). A white noise process Z_t has a constant spectral density $\sigma^2/(2\pi)$. By the preceding theorem the moving average $X_t = Z_t + \theta Z_{t-1}$ has spectral density

$$f_X(\lambda) = |1 + \theta e^{-i\lambda}|^2 \frac{\sigma^2}{2\pi} = (1 + 2\theta \cos \lambda + \theta^2) \frac{\sigma^2}{2\pi}.$$

If $\theta > 0$, then the small frequencies dominate, whereas the bigger frequencies are more important if $\theta < 0$. This suggests that the sample paths of this time series will be more wiggly if $\theta < 0$. However, in both cases all frequencies are present in the signal. □

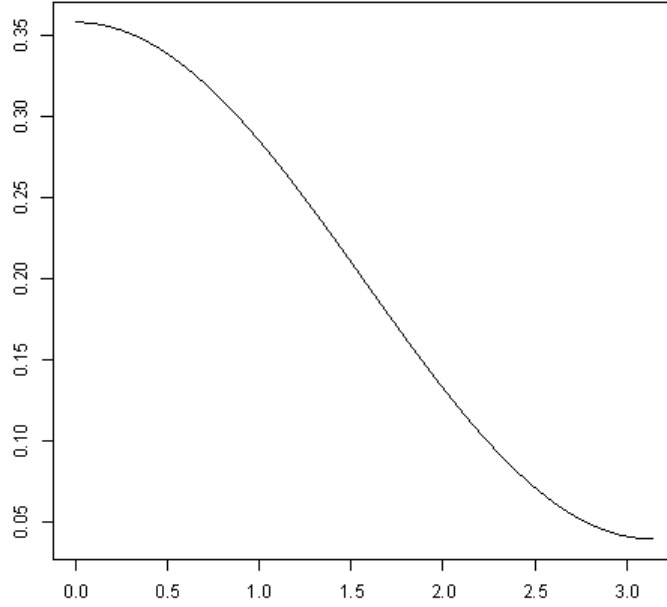

Figure 6.1. Spectral density of the moving average $X_t = Z_t + .5Z_{t-1}$, for $\sigma^2 = 1$.

6.13 Example. The complex-valued process $X_t = Ae^{i\lambda t}$ for a mean zero variable A and $\lambda \in (-\pi, \pi]$ has covariance function

$$\gamma_X(h) = \text{cov}(Ae^{i\lambda(t+h)}, Ae^{i\lambda t}) = e^{ih\lambda} \mathbb{E}|A|^2.$$

The corresponding spectral measure is the 1-point measure F_X with $F_X\{\lambda\} = \mathbb{E}|A|^2$. Therefore, the filtered series $Y_t = \sum_j \psi_j X_{t-j}$ has spectral measure the 1-point measure with $F_Y\{\lambda\} = |\psi(\lambda)|^2 \mathbb{E}|A|^2$. By direct calculation we find that

$$Y_t = \sum_j \psi_j Ae^{i\lambda(t-j)} = Ae^{i\lambda t} \psi(\lambda) = \psi(\lambda) X_t.$$

This suggests an interpretation for the term “transfer function”. Filtering a “pure signal” $Ae^{it\lambda}$ of a single frequency apparently yields another signal of the same single frequency, but the amplitude of the signal changes by multiplication with the factor $\psi(\lambda)$. If $\psi(\lambda) = 0$, then the frequency is “not transmitted”, whereas values of $|\psi(\lambda)|$ bigger or smaller than 1 mean that the frequency λ is amplified or weakened. \square

6.14 EXERCISE. Find the spectral measure of $X_t = Ae^{i\lambda t}$ for λ not necessarily belonging to $(-\pi, \pi]$.

To give a further interpretation to the spectral measure consider a *band pass filter*. This is a filter with transfer function of the form

$$\psi(\lambda) = \begin{cases} 0, & \text{if } |\lambda - \lambda_0| > \delta, \\ 1, & \text{if } |\lambda - \lambda_0| \leq \delta, \end{cases}$$

for a fixed frequency λ_0 and fixed *band width* 2δ . According to Example 6.13 this filter “kills” all the signals $Ae^{i\lambda t}$ of frequencies λ outside the interval $[\lambda_0 - \delta, \lambda_0 + \delta]$ and transmits all signals $Ae^{i\lambda t}$ for λ inside this range unchanged. The spectral density of the filtered signal $Y_t = \sum_j \psi_j X_{t-j}$ relates to the spectral density of the original signal X_t (if there exists one) as

$$f_Y(\lambda) = |\psi(\lambda)|^2 f_X(\lambda) = \begin{cases} 0, & \text{if } |\lambda - \lambda_0| > \delta, \\ f_X(\lambda), & \text{if } |\lambda - \lambda_0| \leq \delta. \end{cases}$$

Now think of X_t as a signal composed of many frequencies. The band pass filter transmits only the subsignals of frequencies in the interval $[\lambda_0 - \delta, \lambda_0 + \delta]$. This explains that the spectral density of the filtered sequence Y_t vanishes outside this interval. For small $\delta > 0$,

$$\text{var } Y_t = \gamma_Y(0) = \int_{-\pi}^{\pi} f_Y(\lambda) d\lambda = \int_{\lambda_0 - \delta}^{\lambda_0 + \delta} f_X(\lambda) d\lambda \approx 2\delta f_X(\lambda_0).$$

We interpret this as saying that $f_X(\lambda_0)$ is proportional to the variance of the subsignals in X_t of frequency λ_0 . The total variance $\text{var } X_t = \gamma_X(0) = \int_{-\pi}^{\pi} f_X(\lambda) d\lambda$ in the signal X_t is the total area under the spectral density. This can be viewed as the sum of the variances of the subsignals of frequencies λ , the area under f_X between $\lambda_0 - \delta$ and $\lambda_0 + \delta$ being the variance of the subsignals of frequencies in this interval.

A band pass filter is a theoretical filter: in practice it is not possible to filter out an exact range of frequencies. Electronic devices will not filter frequencies close to the borders of the band correctly. There are several popular designs that balance a sharp transition of the transfer function to zero to constancy on the “pass band” (cf. Example 6.20). On a computer only finite filters can be implemented (the ones with only finitely many nonzero filter coefficients ψ_j). These have transfer functions that are a finite linear combination of sines and cosines, and hence are smooth and cannot jump, in contrast to the indicator function corresponding to a band pass filter.

The filter coefficients ψ_j relate to the transfer function $\psi(\lambda)$ in the same way as the auto-covariances $\gamma_X(h)$ relate to the spectral density $f_X(h)$, apart from a factor 2π . Thus, to find the filter coefficients of a given transfer function ψ , it suffices to apply the Fourier inversion formula

$$\psi_j = \frac{1}{2\pi} \int_{-\pi}^{\pi} e^{ij\lambda} \psi(\lambda) d\lambda.$$

6.15 EXERCISE. Show that the filter coefficients of a band pass filter with $(\lambda_0 - \delta, \lambda_0 + \delta) \subset (0, \pi)$ are given by $\psi_j = e^{i\lambda_0 j} \sin(\delta j) / (\pi j)$.

6.16 Example (Low frequency and trend). An apparent trend in observed data X_1, \dots, X_n could be modelled as a real trend in a nonstationary time series, but could

alternatively be viewed as the beginning of a long cycle. In practice, where we get to see only a finite stretch of a time series, low frequency cycles and slowly moving trends cannot be discriminated. It was seen in Chapter 1 that differencing $Y_t = X_t - X_{t-1}$ of a time series X_t removes a linear trend, and repeated differencing removes higher order polynomial trends. In view of the preceding observation the differencing filter should remove, to a certain extent, low frequencies.

The differencing filter has transfer function

$$\psi(\lambda) = 1 - e^{-i\lambda} = 2ie^{-i\lambda/2} \sin \frac{\lambda}{2}.$$

The absolute value $|\psi(\lambda)|$ of this transfer function increases from 0 at 0 to its maximum value at π (see Figure 6.2). Thus, indeed, it filters away low frequencies, albeit only with partial success. \square

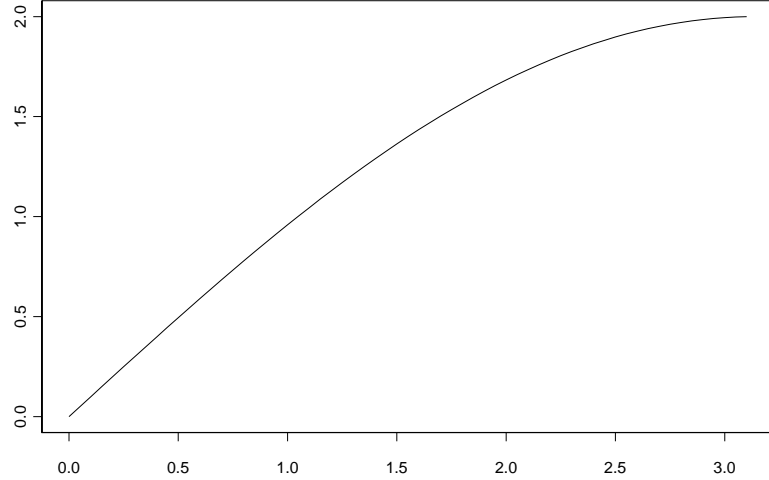

Figure 6.2. Absolute value of the transfer function of the difference filter.

6.17 Example (Averaging). The averaging filter $Y_t = (2M + 1)^{-1} \sum_{j=-M}^M X_{t-j}$ has transfer function

$$\psi(\lambda) = \frac{1}{2M + 1} \sum_{j=-M}^M e^{-ij\lambda} = \frac{\sin((M + \frac{1}{2})\lambda)}{(2M + 1) \sin(\frac{1}{2}\lambda)}.$$

(The expression on the right is defined by continuity, as 1, at $\lambda = 0$.) This function is proportional to the *Dirichlet kernel*, which is the function obtained by replacing the factor $2M + 1$ by 2π . From a picture of this kernel we conclude that averaging removes

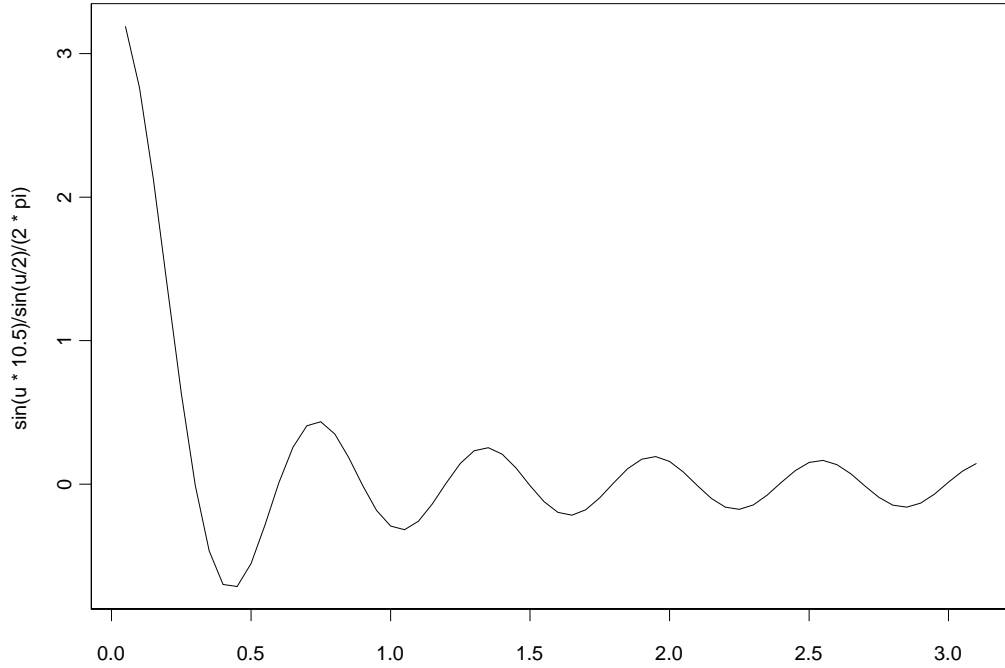

Figure 6.3. Dirichlet kernel of order $M = 10$.

high frequencies to a certain extent (and in an uneven manner depending on M), but retains low frequencies. \square

6.18 EXERCISE. Express the variance of Y_t in the preceding example in ψ and the spectral density of the time series X_t (assuming that there is one). What happens if $M \rightarrow \infty$? Which conclusion can you draw? Does this remain true if the series X_t does not have a spectral density? [Verify that $|\psi(\lambda)| \leq 1$ for every λ and M , and that $\psi(\lambda) \rightarrow 0$ as $M \rightarrow \infty$ for every 0 .]

6.19 EXERCISE. Find the transfer function of the filter $Y_t = X_t - X_{t-12}$. Interpret the result.

6.20 Example (Butterworth filter). The *Butterworth filter* of order n with cut-off ω has transfer function satisfying

$$\psi(\lambda) = \left(\prod_{i=1}^n (i\lambda - \omega e^{(2k+n-1)\pi i/(2n)}) \right)^{-1}, \quad |\psi(\lambda)|^2 = \left(1 + (\lambda/\omega)^{2n} \right)^{-1}.$$

It is a low-pass filter: the function $|\psi(\lambda)|$ is approximately constant equal to 1 on $[0, \omega)$ and approximately 0 on $(\omega, \pi]$. The transition from 1 to 0 is sharper if n is larger. The derivatives of $|\psi(\lambda)|^2$ up to order $2n - 1$ vanish, making the function “maximally flat” on the intervals where it takes unit or zero values. It pays for this desirable property by a transition from 1 to 0 that is slower than some other popular filters such as the Chebyshev.

The Butterworth filter is popular in signal analysis. It was proposed by Butterworth in 1930 as an electrical circuit, illustrated in Figure 6.4 for the order $n = 3$. \square

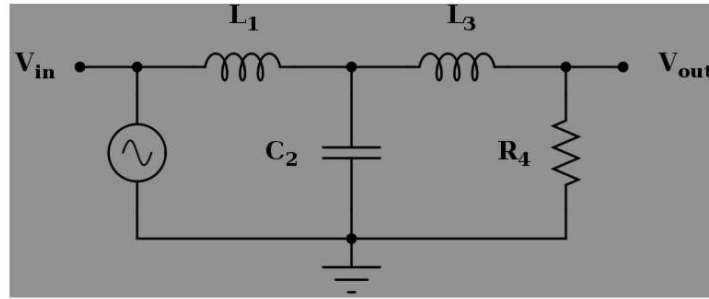

Figure 6.4. Electrical circuit implementing a Butterworth filter of order 3, if the capacitor C is set of $4/3$ farad, the resistor R to 1 Ohm and the inductors $L1$ and $L2$ to $3/2$ and 1 Henry, respectively.

Instead of in terms of frequencies we can also think in *periods*. A series of the form $t \mapsto e^{i\lambda t}$ repeats itself after $2\pi/\lambda$ instants of time. Therefore, the period is defined as

$$\text{period} = \frac{2\pi}{\text{frequency}}.$$

Most monthly time series (one observation per month) have a period effect of 12 months. If so, this will be visible as a peak in the spectrum at the frequency $2\pi/12 = \pi/6$.[‡] Often the 12-month cycle is not completely regular. This may produce additional (but smaller) peaks at the *harmonic frequencies* $2\pi/6, 3\pi/6, \dots$, or $\pi/12, \pi/18, \dots$.

It is surprising at first that the highest possible frequency is π , the so-called *Nyquist frequency*. This is caused by the fact that the series is measured only at discrete time points. Very rapid fluctuations fall completely between the measurement times and hence cannot be observed. The Nyquist frequency π corresponds to a period of $2\pi/\pi = 2$ time instants and this is clearly the smallest period that is observable. The next section sheds more light on this.

[‡] That this is a complicated number is an inconvenient consequence of our convention to define the spectrum on the interval $(-\pi, \pi]$. This can be repaired. For instance, the Splus package produces spectral plots with the frequencies rescaled to the interval $(-\frac{1}{2}, \frac{1}{2}]$. Then a 12-month period gives a peak at $1/12$.

* 6.2 Aliasing

In practice a (discrete-time) time series often arises by measuring an underlying continuous-time process at discrete time instants, an operation called *sampling*. For regularly spaced time instants the *sampling frequency* is defined as the number of measurements per time unit. The more we sample the better, of course, but practical considerations, such as computer storage of the data, will impose restrictions. In this section we study the effect of sampling on the spectrum of a time series.

Consider a time series $(X_t: t \in \mathbb{Z})$ obtained by sampling a continuous time stochastic process $(Y_t: t \in \mathbb{R})$ at times $-\delta, 0, \delta, 2\delta, \dots$ for a sampling interval $\delta > 0$: $X_t = Y_{t\delta}$. The continuous time process Y_t is said to be *second order stationary* if its expectation is constant and the autocovariances $\text{cov}(Y_{t+h}, Y_t)$ do not depend on t , so that its (continuous time) autocovariance function can be defined by, for $h \in \mathbb{R}$,

$$\gamma_Y(h) = \text{cov}(Y_{t+h}, Y_t).$$

By *Bochner's theorem*, provided that it is continuous, such a covariance function can always be represented by a finite Borel measure F_Y on \mathbb{R} in the form

$$\gamma_Y(h) = \int_{-\infty}^{\infty} e^{ih\lambda} dF_Y(\lambda), \quad h \in \mathbb{R}.$$

This is similar to Herglotz' theorem, the important difference being that the representation uses all frequencies in \mathbb{R} , not just an interval of length 2π , and is valid for the continuum of lags $h \in \mathbb{R}$.^b

6.21 Lemma. *The skeleton $(X_t: t \in \mathbb{Z}) = (Y_{t\delta}: t \in \mathbb{Z})$ of a continuous time stationary process $(Y_t: t \in \mathbb{Z})$ with spectral measure F_Y possesses spectral measure F_X given by*

$$F_X(B) = \sum_{k \in \mathbb{Z}} F_Y\left(\frac{B + k 2\pi}{\delta}\right).$$

Proof. The covariance function of the time series X_t can be written $\gamma_X(h) = \gamma_Y(h\delta) = \int e^{ih\delta\lambda} dF_Y(\lambda)$. The function $\lambda \mapsto e^{ih\delta\lambda}$ is periodic with period $2\pi/\delta$, for every $h \in \mathbb{Z}$. It is therefore identical on the intervals $\dots, (-3\pi/\delta, -\pi/\delta], (-\pi/\delta, \pi/\delta], (\pi/\delta, 3\pi/\delta], \dots$ and the integral over \mathbb{R} of the function relative to F_Y can be written as the integral of the function over the interval $(-\pi/\delta, \pi/\delta]$ relative to the infinite sum of the translates of the restrictions of the measure F_Y to the intervals. Finally we rescale $\delta\lambda \rightarrow \lambda$. ■

The preceding lemma shows that the spectral weights of the continuous time process Y_t at a frequency not in the interval $(-\pi/\delta, \pi/\delta]$ contribute to the spectral weights of the sampled process at the frequency modulo $2\pi/\delta$. In particular, if $\delta = 1$ the frequencies bigger than the Nyquist frequency, which may be “present” in the signal Y_t , contribute to the spectrum of the sampled process at frequencies modulo 2π . This effect, which

^b For a proof of Bochner's theorem, along the lines of the proof of Herglotz theorem, see pages 275–277 of *Gnedenko (1962)*.

is referred to as *aliasing*, is often considered undesirable, because it is impossible to separate the contributions of the frequencies that are really present (below the Nyquist frequency) from the “aliased” frequencies. Aliasing typically leads to an overall higher spectral density, which is equivalent to a bigger noise content of the signal.

For this reason, if it is possible, a signal should be low-pass filtered before sampling it. With continuous time electronic signals this filtering step is often achieved at the measuring time by passing the signal through a physical, electronic device, before sampling or digitizing it. If for some reason an already discretized signal must be “down-sampled”, then it can also be useful to low-pass filter the signal first, which can be achieved by just applying a linear filter with the appropriate transfer function.

* 6.3 Nonsummable filters

For coefficients ψ_j with $\sum_j |\psi_j| < \infty$, the filtered series $\sum_j \psi_j X_{t-j}$ is well defined for any stationary time series X_t . Unfortunately, not all filters have summable coefficients. An embarrassing example is the band pass filter considered previously, for which the filter coefficients tend to zero at the speed $|\psi_j| \sim 1/j$.

In fact, if a sequence of filter coefficients is summable, then the series $\sum_j \psi_j e^{ij\lambda}$ converges uniformly, and hence the corresponding transfer function must be continuous. The transfer function $\lambda \mapsto \psi(\lambda) = 1_{[\lambda_0-\delta, \lambda_0+\delta]}(\lambda)$ of the band pass filter has two jumps. In such a case, the series $\sum_j \psi_j e^{-ij\lambda}$ may still be well defined, for instance as a limit in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$, and define a valid transfer function. To handle such examples it is worthwhile to generalize Theorem 6.11 (and Lemma 1.29).

6.22 Theorem. *Let X_t be a stationary zero-mean time series with spectral measure F_X , defined on the probability space $(\Omega, \mathcal{U}, \mathbb{P})$. Then the series $\psi(\lambda) = \sum_j \psi_j e^{-i\lambda j}$ converges in $L_2(F_X)$ if and only if $Y_t = \sum_j \psi_j X_{t-j}$ converges in $L_2(\Omega, \mathcal{U}, \mathbb{P})$ for some t (and then for every $t \in \mathbb{Z}$) and in that case*

$$dF_Y(\lambda) = |\psi(\lambda)|^2 dF_X(\lambda).$$

Proof. For $0 \leq m \leq n$ let $\psi_j^{m,n}$ be equal to ψ_j for $m \leq |j| \leq n$ and be 0 otherwise, and define $Y_t^{m,n}$ as the series X_t filtered by the coefficients $\psi_j^{m,n}$. Then certainly $\sum_j |\psi_j^{m,n}| < \infty$ for every fixed pair (m, n) and hence we can apply Lemma 1.29 and Theorem 6.11 to the series $Y_t^{m,n}$. This yields

$$\begin{aligned} \mathbb{E} \left| \sum_{m \leq |j| \leq n} \psi_j X_{t-j} \right|^2 &= \mathbb{E} |Y_t^{m,n}|^2 = \gamma_{Y^{m,n}}(0) \\ &= \int_{(-\pi, \pi]} dF_{Y^{m,n}} = \int_{(-\pi, \pi]} \left| \sum_{m \leq |j| \leq n} \psi_j e^{-i\lambda j} \right|^2 dF_X(\lambda). \end{aligned}$$

The left side converges to zero for $m, n \rightarrow \infty$ if and only if the partial sums of the series $Y_t = \sum_j \psi_j X_{t-j}$ form a Cauchy sequence in $L_2(\Omega, \mathcal{U}, \mathbb{P})$. The right side converges to zero

if and only if the partial sums of the sequence $\sum_j \psi_j e^{-i\lambda j}$ form a Cauchy sequence in $L_2(F_X)$. The first assertion of the theorem now follows, because both spaces are complete.

To prove the second assertion, we first note that, by Theorem 6.11,

$$\text{cov}\left(\sum_{|j|\leq n} \psi_j X_{t+h-j}, \sum_{|j|\leq n} \psi_j X_{t-j}\right) = \gamma_{Y^{0,n}}(h) = \int_{(-\pi, \pi]} \left| \sum_{|j|\leq n} \psi_j e^{-i\lambda j} \right|^2 e^{ih\lambda} dF_X(\lambda).$$

We now take limits of the left and right sides as $n \rightarrow \infty$ to find that $\gamma_Y(h) = \int_{(-\pi, \pi]} |\psi(\lambda)|^2 e^{ih\lambda} dF_X(\lambda)$, for every h . ■

6.23 Example. If the filter coefficients satisfy $\sum_j |\psi_j|^2 < \infty$ (which is weaker than absolute convergence), then the series $\sum_j \psi_j e^{-ij\lambda}$ converges in $L_2((-\pi, \pi], \mathcal{B}, \lambda)$. Consequently, the series also converges in $L_2(F_X)$ for every spectral measure F_X that possesses a bounded density.

Thus, in many cases a sequence of square-summable coefficients defines a valid filter. A particular example is a band pass filter, for which $|\psi_j| = O(1/|j|)$ as $j \rightarrow \pm\infty$. □

* 6.4 Spectral Decomposition

In the preceding section we interpreted the mass $F_X(I)$ that the spectral distribution gives to an interval I as the size of the contribution of the components of frequencies $\lambda \in I$ to the signal $t \mapsto X_t$. In this section we give a precise mathematical meaning to this idea. We show that a given stationary time series X_t can be written as a randomly weighted sum of single frequency signals $e^{i\lambda t}$.

This decomposition is simple in the case of a discrete spectral measure. For given uncorrelated, zero-mean random variables Z_1, \dots, Z_k and numbers $\lambda_1, \dots, \lambda_k \in (-\pi, \pi]$ the process

$$X_t = \sum_{j=1}^k Z_j e^{i\lambda_j t}$$

possesses as spectral measure F_X the discrete measure with point masses of sizes $F_X\{\lambda_j\} = E|Z_j|^2$ at the frequencies $\lambda_1, \dots, \lambda_k$ (and no other mass). The series X_t is the sum of uncorrelated, single-frequency signals of stochastic amplitudes $|Z_j|$. This is called the *spectral decomposition* of the series X_t . We prove below that this construction can be reversed: given a mean zero, stationary time series X_t with discrete spectral measure as given, there exist mean zero uncorrelated (complex-valued) random variables Z_1, \dots, Z_k with variances $F_X\{\lambda_j\}$ such that the decomposition is valid.

This justifies the interpretation of the spectrum given in the preceding section. The possibility of the decomposition is surprising in that the spectral measure only involves the auto-covariance function of a time series, whereas the spectral decomposition is a decomposition of the sample paths of the time series: if the series X_t is defined on a

given probability space (Ω, \mathcal{U}, P) , then so are the random variables Z_j and the preceding spectral decomposition may be understood as being valid for (almost) every $\omega \in \Omega$. This can be true, of course, only if the variables Z_1, \dots, Z_k also have other properties besides the ones described. The spectral theorem below does not give any information about these further properties. For instance, even though uncorrelated, the Z_j need not be independent. This restricts the usefulness of the spectral decomposition, but we could not expect more. Because the spectrum only involves second moment properties, it leaves most of the distribution of a series undescribed. An important exception are Gaussian times series, for which the first and second moments, and hence the mean and the spectral distribution, describe the complete distribution.

The spectral decomposition is not restricted to time series with discrete spectral measures. However, in general, the spectral decomposition involves a continuum of frequencies and the sum becomes an integral

$$X_t = \int_{(-\pi, \pi]} e^{i\lambda t} dZ(\lambda).$$

A technical complication is that such an integral, relative to a “random measure” Z , is not defined in ordinary measure theory. We must first give it a meaning.

6.24 Definition. A random measure with orthogonal increments Z is a collection $(Z(B): B \in \mathcal{B})$ of mean zero, complex random variables $Z(B)$ indexed by the Borel sets \mathcal{B} in $(-\pi, \pi]$ defined on some probability space (Ω, \mathcal{U}, P) such that, for some finite Borel measure μ on $(-\pi, \pi]$,

$$\text{cov}(Z(B_1), Z(B_2)) = \mu(B_1 \cap B_2), \quad \text{every } B_1, B_2 \in \mathcal{B}.$$

This definition does not appear to include a basic requirement of a measure: that the measure of a countable union of disjoint sets is the sum of the measures of the individual sets. However, this is implied by the covariance property, which says that the linear extension of the map $1_B \mapsto Z(B)$ is an isometry from $L_2(\mu)$ into $L_2(\Omega, \mathcal{U}, P)$.

6.25 EXERCISE. Let Z be a random measure with orthogonal increments. Show that $Z(\cup_j B_j) = \sum_j Z(B_j)$ in mean square, whenever B_1, B_2, \dots is a sequence of pairwise disjoint Borel sets.

6.26 EXERCISE. Let Z be a random measure with orthogonal increments and define $Z_\lambda = Z(-\pi, \lambda]$. Show that $(Z_\lambda: \lambda \in (-\pi, \pi])$ is a stochastic process with uncorrelated increments: for $\lambda_1 < \lambda_2 \leq \lambda_3 < \lambda_4$ the variables $Z_{\lambda_4} - Z_{\lambda_3}$ and $Z_{\lambda_2} - Z_{\lambda_1}$ are uncorrelated. This explains the phrase “with orthogonal increments”.

* **6.27 EXERCISE.** Suppose that Z_λ is a mean zero stochastic process with finite second moments and uncorrelated increments. Show that this process corresponds to a random measure with orthogonal increments as in the preceding exercise. [This asks you to reconstruct the random measure Z from the weights $Z_\lambda = Z(-\pi, \lambda]$ it gives to cells, similarly as an ordinary measure can be reconstructed from its distribution function.

The construction below will immediately give us the complete random measure as in Definition 6.24. So it is not really helpful to go through the somewhat tedious details of this construction, although many authors start from distribution functions rather than measures.]

Next we define an “integral” $\int f dZ$ for given functions $f: (-\pi, \pi] \rightarrow \mathbb{C}$. For an indicator function $f = 1_B$ of a Borel set B , we define, in analogy with an ordinary integral, $\int 1_B dZ = Z(B)$. Because we wish the integral to be linear, we are lead to the definition

$$\int \sum_j \alpha_j 1_{B_j} dZ = \sum_j \alpha_j Z(B_j),$$

for every finite collections of complex numbers α_j and Borel sets B_j . This determines the integral for many, but not all functions f . We extend its domain by continuity: we require that $\int f_n dZ \rightarrow \int f dZ$ whenever $f_n \rightarrow f$ in $L_2(\mu)$. The following lemma shows that these definitions and requirements can be consistently made, and serves as a definition of $\int f dZ$.

6.28 Lemma. *For every random measure with orthogonal increments Z there exists a unique map, denoted $f \mapsto \int f dZ$, from $L_2(\mu)$ into $L_2(\Omega, \mathcal{U}, P)$ with the properties*

- (i) $\int 1_B dZ = Z(B)$;
- (ii) $\int (\alpha f + \beta g) dZ = \alpha \int f dZ + \beta \int g dZ$;
- (iii) $E \left| \int f dZ \right|^2 = \int |f|^2 d\mu$.

In other words, the map $f \mapsto \int f dZ$ is a linear isometry such that $1_B \mapsto Z(B)$.

Proof. By the defining property of Z , for any complex numbers α_i and Borel sets B_i ,

$$E \left| \sum_{i=1}^k \alpha_i Z(B_i) \right|^2 = \sum_i \sum_j \alpha_i \bar{\alpha}_j \text{cov}(Z(B_i), Z(B_j)) = \int \left| \sum_{j=1}^k \alpha_j 1_{B_j} \right|^2 d\mu.$$

For f a simple function of the form $f = \sum_i \alpha_i 1_{B_i}$, we define $\int f dZ$ as $\sum_i \alpha_i Z(B_i)$. This is well defined, for, if f also has the representation $f = \sum_j \beta_j 1_{D_j}$, then $\sum_i \alpha_i Z(B_i) = \sum_j \beta_j Z(D_j)$ almost surely. This follows by applying the preceding identity to $\sum_i \alpha_i Z(B_i) - \sum_j \beta_j Z(D_j)$.

The “integral” $\int f dZ$ that is now defined on the domain of all simple functions f trivially satisfies (i) and (ii), while (iii) is exactly the identity in the preceding display. The proof is complete upon showing that the map $f \mapsto \int f dZ$ can be extended from the domain of simple functions to the domain $L_2(\mu)$, meanwhile retaining the properties (i)–(iii).

We extend the map by continuity. For every $f \in L_2(\mu)$ there exists a sequence of simple functions f_n such that $\int |f_n - f|^2 d\mu \rightarrow 0$. We define $\int f dZ$ as the limit in $L_2(\Omega, \mathcal{U}, P)$ of the sequence $\int f_n dZ$. This is well defined. First, the limit exists, because, by the linearity of the integral and the identity,

$$E \left| \int f_n dZ - \int f_m dZ \right|^2 = \int |f_n - f_m|^2 d\mu,$$

since $f_n - f_m$ is a simple function. Because f_n is a Cauchy sequence in $L_2(\mu)$, the right side converges to zero as $m, n \rightarrow \infty$. We conclude that $\int f_n dZ$ is a Cauchy sequence in $L_2(\Omega, \mathcal{U}, P)$ and hence it has a limit by the completeness of this space. Second, the definition of $\int f dZ$ does not depend on the particular sequence $f_n \rightarrow f$ we use. This follows, because given another sequence of simple functions $g_n \rightarrow f$, we have $\int |f_n - g_n|^2 d\mu \rightarrow 0$ and hence $E \left| \int f_n dZ - \int g_n dZ \right|^2 \rightarrow 0$.

We conclude the proof by noting that the properties (i)–(iii) are retained under taking limits. ■

6.29 Definition (Stochastic integral). The stochastic integral $\int f dZ$ of a function $f \in L_2(\mu)$ relative to a random measure with orthogonal increments Z as in Definition 6.24 is given by the map defined in Lemma 6.28. An alternative notation is $Z(f)$.

Warning. This integral is constructed in a similar way as the *Itô integral* in stochastic analysis, but it is not the same. The process Z in the decomposition $Z(0, \lambda] = Z_\lambda - Z_0$ of a random measure with orthogonal increments is not necessarily a semimartingale. On the other hand, the integral $\int f dZ$ is defined here only for deterministic integrands.

6.30 EXERCISE. Show that a linear isometry $\Phi: \mathbb{H}_1 \rightarrow \mathbb{H}_2$ between two Hilbert spaces \mathbb{H}_1 and \mathbb{H}_2 retains inner products, i.e. $\langle \Phi(f_1), \Phi(f_2) \rangle_2 = \langle f_1, f_2 \rangle_1$. Conclude that $\text{cov}(\int f dZ, \int g dZ) = \int f \bar{g} d\mu$.

We are now ready to derive the spectral decomposition for a general stationary time series X_t . Let $L_2(X_t: t \in \mathbb{Z})$ be the closed, linear span of the elements of the time series in $L_2(\Omega, \mathcal{U}, P)$ (i.e. the closure of the linear span of the set $\{X_t: t \in \mathbb{Z}\}$).

6.31 Theorem (Spectral representation). For any mean zero stationary time series X_t with spectral distribution F_X there exists a random measure Z with orthogonal increments relative to the measure F_X such that $\{Z(B): B \in \mathcal{B}\} \subset L_2(X_t: t \in \mathbb{Z})$ and such that $X_t = \int e^{i\lambda t} dZ(\lambda)$ almost surely for every $t \in \mathbb{Z}$.

Proof. By the definition of the spectral measure F_X we have, for every finite collections of complex numbers α_j and integers t_j ,

$$E \left| \sum \alpha_j X_{t_j} \right|^2 = \sum_i \sum_j \alpha_i \bar{\alpha}_j \gamma_X(t_i - t_j) = \int \left| \sum \alpha_j e^{it_j \lambda} \right|^2 dF_X(\lambda).$$

Now define a map $\Phi: L_2(F_X) \rightarrow L_2(X_t: t \in \mathbb{Z})$ as follows. For f of the form $f = \sum_j \alpha_j e^{it_j \lambda}$ define $\Phi(f) = \sum_j \alpha_j X_{t_j}$. By the preceding identity this is well defined. (Check!) Furthermore, Φ is a linear isometry. By the same arguments as in the preceding lemma, it can be extended to a linear isometry on the closure of the space of all functions $\sum_j \alpha_j e^{it_j \lambda}$. By Féjer's theorem from Fourier theory, this closure contains at least all Lipschitz periodic functions. By measure theory this collection is dense in

$L_2(F_X)$. Thus the closure is all of $L_2(F_X)$. In particular, it contains all indicator functions 1_B of Borel sets B . Define $Z(B) = \Phi(1_B)$. Because Φ is a linear isometry, it retains inner products and hence

$$\text{cov}(Z(B_1), Z(B_2)) = \langle \Phi(1_{B_1}), \Phi(1_{B_2}) \rangle = \int 1_{B_1} 1_{B_2} dF_X.$$

This shows that Z is a random measure with orthogonal increments. By definition

$$\int \sum_j \alpha_j 1_{B_j} dZ = \sum_j \alpha_j Z(B_j) = \sum_j \alpha_j \Phi(1_{B_j}) = \Phi\left(\sum_j \alpha_j 1_{B_j}\right).$$

Thus $\int f dZ = \Phi(f)$ for every simple function f . Both sides of this identity are linear isometries when seen as functions of $f \in L_2(F_X)$. Hence the identity extends to all $f \in L_2(F_X)$. In particular, we obtain $\int e^{it\lambda} dZ(\lambda) = \Phi(e^{it\lambda}) = X_t$ on choosing $f(\lambda) = e^{it\lambda}$. ■

Thus we have managed to give a precise mathematical formulation to the spectral decomposition

$$X_t = \int_{(-\pi, \pi]} e^{it\lambda} dZ(\lambda)$$

of a mean zero stationary time series X_t . The definition is a bit involved. It may even seem that giving a meaning to the representation was harder than proving its validity. An insightful interpretation is obtained by approximation through Riemann sums. Given a partition $-\pi = \lambda_{0,k} < \lambda_{1,k} < \dots < \lambda_{k,k} = \pi$ and a fixed time $t \in \mathbb{Z}$, consider the function $\lambda \mapsto f_k(\lambda)$ that is piecewise constant, and takes the value $e^{it\lambda_{j,k}}$ on the interval $(\lambda_{j-1,k}, \lambda_{j,k}]$. If the partitions are chosen such that the mesh width of the partitions converges to zero as $k \rightarrow \infty$, then $|f_k(\lambda) - e^{it\lambda}|$ converges to zero, uniformly in $\lambda \in (-\pi, \pi]$, by the uniform continuity of the function $\lambda \mapsto e^{it\lambda}$, and hence $f_k(\lambda) \rightarrow e^{it\lambda}$ in $L_2(F_X)$. Because the stochastic integral $f \mapsto \int f dZ$ is linear, we have $\int f_k dZ = \sum_j e^{it\lambda_{j,k}} Z(\lambda_{j-1,k}, \lambda_{j,k}]$ and because it is an isometry, we find

$$\mathbb{E} \left| X_t - \sum_{j=1}^k e^{it\lambda_{j,k}} Z(\lambda_{j-1,k}, \lambda_{j,k}] \right|^2 = \int |e^{it\lambda} - f_k(\lambda)|^2 dF_X(\lambda) \rightarrow 0.$$

Because the intervals $(\lambda_{j-1,k}, \lambda_{j,k}]$ are pairwise disjoint, the random variables $Z_j := Z(\lambda_{j-1,k}, \lambda_{j,k}]$ are uncorrelated, by the defining property of an orthogonal random measure. Thus the time series X_t can be approximated by a time series of the form $\sum_j Z_j e^{it\lambda_j}$, as in the introduction of this section. The spectral measure $F_X(\lambda_{j-1,k}, \lambda_{j,k}]$ of the interval $(\lambda_{j-1,k}, \lambda_{j,k}]$ is the variance of the random weight Z_j in this decomposition.

6.32 Example (Discrete spectrum). If the spectral measure F_X is discrete with support points $\lambda_1, \dots, \lambda_k$, then the integral on the right in the preceding display (with $\lambda_{j,k} = \lambda_j$) is identically zero. In that case $X_t = \sum_j Z_j e^{i\lambda_j t}$ almost surely for every t , where $Z_j = Z\{\lambda_j\}$. (Note that $Z(\lambda_{j-1}, \lambda_j) = 0$). □

6.33 Example (Gaussian series). If the time series X_t is Gaussian, then all variables in the linear span of the X_t are normally distributed (possibly degenerate) and hence all variables in $L_2(X_t; t \in \mathbb{Z})$ are normally distributed. In that case the variables $Z(B)$ obtained from the random measure Z of the spectral decomposition of X_t are jointly normally distributed. The zero correlation of two variables $Z(B_1)$ and $Z(B_2)$ for disjoint sets B_1 and B_2 now implies independence of these variables. \square

Theorem 6.22 shows how a spectral measure changes under filtering. There is a corresponding result for the spectral decomposition.

6.34 Theorem. Let X_t be a mean zero, stationary time series with spectral measure F_X and associated random measure Z_X , defined on some probability space (Ω, \mathcal{U}, P) . If $\psi(\lambda) = \sum_j \psi_j e^{-i\lambda j}$ converges in $L_2(F_X)$, then $Y_t = \sum_j \psi_j X_{t-j}$ converges in $L_2(\Omega, \mathcal{U}, P)$ and has spectral measure F_Y and associated random measure Z_Y such that, for every $f \in L_2(F_Y)$,

$$\int f dZ_Y = \int f \psi dZ_X.$$

Proof. The series Y_t converges by and has spectral measure F_Y with density $|\psi(\lambda)|^2$ relative to F_X , by Theorem 6.22. By definition,

$$\int e^{it\lambda} dZ_Y(\lambda) = Y_t = \sum_j \psi_j \int e^{i(t-j)\lambda} dZ_X(\lambda) = \int e^{it\lambda} \psi(\lambda) dZ_X(\lambda),$$

where in the last step changing the order of integration and summation is justified by the convergence of the series $\sum_j \psi_j e^{i(t-j)\lambda}$ in $L_2(F_X)$ and the continuity of the stochastic integral $f \mapsto \int f dZ_X$. We conclude that the identity of the theorem is satisfied for every f of the form $f(\lambda) = e^{it\lambda}$. Both sides of the identity are linear in f and isometries on the domain $f \in L_2(F_Y)$. Because the linear span of the functions $\lambda \mapsto e^{it\lambda}$ for $t \in \mathbb{Z}$ is dense in $L_2(F_Y)$, the identity extends to all of $L_2(F_Y)$. \blacksquare

The spectral decomposition $X_t = \int e^{i\lambda t} dZ(\lambda)$ is valid for both real and complex time series. Because the representation is in terms of the complex functions $e^{it\lambda}$, the spectral random measure Z of a real time series is typically complex valued. The following lemma shows that it is complex-conjugate. Abbreviate $\int f dZ(\lambda)$ to $Z(f)$, and given a function $f: (-\pi, \pi] \rightarrow \mathbb{C}$ let f_- be the reflection (of its periodic extension): $f_-(\lambda) = f(-\lambda)$ for $\lambda \in (-\pi, \pi)$ and $f_-(\pi) = f(\pi)$.

6.35 Lemma. The spectral random measure of a real time series X_t satisfies $\overline{Z(f)} = Z(\overline{f_-})$ almost surely, for every $f \in L(F_X)$. In particular $\overline{Z(B)} = Z(-B)$ almost surely, for every Borel set $B \subset (-\pi, \pi)$. Furthermore, for any $f, g \in L_2(F_X)$,

$$E \operatorname{Re} Z(f) \operatorname{Re} Z(g) = \frac{1}{4} \int (f + \overline{f_-})(\overline{g} + g_-) dF_X,$$

$$E \operatorname{Re} Z(f) \operatorname{Im} Z(g) = \frac{1}{4} \int (f + \overline{f_-})(\overline{g} - g_-) dF_X,$$

$$E \operatorname{Im} Z(f) \operatorname{Im} Z(g) = \frac{1}{4} \int (f - \overline{f_-})(\overline{g} - g_-) dF_X.$$

In particular, if f and g are real and vanish outside $(0, \pi)$, then $E \operatorname{Re} Z(f) \operatorname{Im} Z(g) = 0$ and $E \operatorname{Re} Z(f) \operatorname{Re} Z(g) = E \operatorname{Im} Z(f) \operatorname{Im} Z(g)$.

Proof. If the Fourier series $\sum_j f_j e^{ijt\lambda}$, where $f_j = (2\pi)^{-1} \int e^{-ij\lambda} f(\lambda) d\lambda$, converges in $L_2(F_X)$ to the function f , then by the continuity of the random spectral measure

$$Z(f) = \sum_j f_j Z(e^{ij\lambda}) = \sum_j f_j X_j,$$

where the convergence of the infinite series is in $L_2(X_t: t \in \mathbb{Z})$. Because the Fourier coefficients of \bar{f}_- are equal to \bar{f}_j , it then follows that

$$\overline{Z(f)} = \sum_j \bar{f}_j X_j = Z(\bar{f}_-).$$

This proves the conjugate symmetry of Z for functions f of this type. The convergence (and hence the conjugate symmetry) is certainly true for every periodic, Lipschitz function f , for which the convergence of the Fourier series is uniform. A general f can be approximated in $L_2(F_X)$ by a sequence f_n of Lipschitz, periodic functions, and then the sequence f_{n-} tends in $L_2(F_X)$ to f_- , in view of the symmetry of F_X . Thus the conjugate symmetry extends to any such function.

The expressions for the second moments of the real and imaginary parts follow upon writing $\operatorname{Re} Z(f) = \frac{1}{2}(Z(f) + \overline{Z(f)}) = \frac{1}{2}Z(f + \bar{f}_-)$ and $\operatorname{Im} Z(f) = \frac{1}{2}(Z(f) - \overline{Z(f)}) = \frac{1}{2}Z(f - \bar{f}_-)$. In the particular case that f and g are real and vanish outside $(0, \pi)$, the function $f + \bar{f}_-$ is symmetric, the function $g - \bar{g}_-$ is anti-symmetric, and $(f + \bar{f}_-)(g + \bar{g}_-) = (f - \bar{f}_-)(g - \bar{g}_-)$. Together with the symmetry of F_X this yields the last assertion. ■

The last assertion of the preceding lemma shows that the random vectors $(\operatorname{Re} Z(f_1), \dots, \operatorname{Re} Z(f_k))$ and $(\operatorname{Im} Z(f_1), \dots, \operatorname{Im} Z(f_k))$ are uncorrelated and have equal covariance matrix, for any real functions f_1, \dots, f_k in $L_2(F_X)$ that vanish outside $(0, \pi)$. This implies that the vector of combined real and imaginary parts of the complex random vector $(Z(f_1), \dots, Z(f_k))$ possesses a covariance matrix of the form (1.3), for functions f_1, \dots, f_k of the special type considered, and then also for general functions that vanish at 0 and π by the linearity of Z in f . In particular, if the time series X_t is real and Gaussian, then the complex random vector $(Z(f_1), \dots, Z(f_k))$ possesses a complex normal distribution $N(0, \Sigma)$ for Σ the matrix with (i, j) th element $\int f_i \bar{f}_j dF_X$.

6.36 EXERCISE. Show that for a real time series $Z\{0\}$ and $Z\{\pi\}$ are real. Conclude that these variables are complex normally distributed only if they are 0. [One proof can be based on the law of large numbers in Section 7.1, which exhibits $1_{\{0\}}$ as a limit of real linear combinations of functions $\lambda \mapsto e^{it\lambda}$; the same linear combinations of the functions $\lambda \mapsto e^{it(\lambda-\pi)} = (-1)^t e^{it\lambda}$ tend to $1_{\{\pi\}}$.]

6.37 EXERCISE (Inversion formula). Show that, for any continuity points $0 \leq a < b \leq \pi$ of F_X ,

$$\frac{1}{2\pi} \sum_{t=-n}^n X_t \int_a^b e^{-it\lambda} d\lambda \rightarrow Z(a, b], \quad \text{in } L_2.$$

[Note that $(2\pi)^{-1} \int_a^b e^{-it\lambda} d\lambda$ are the Fourier coefficients of the function $1_{(a,b]}\cdot$]

* 6.5 Multivariate Spectra

If spectral analysis of univariate time series is hard, spectral analysis of multivariate time series is an art. It concerns not only “frequencies present in a single signal”, but also “dependencies between signals at given frequencies”.

This difficulty concerns the interpretation only: the mathematical theory does not pose new challenges. The covariance function γ_X of a vector-valued times series X_t is matrix-valued. If the series $\sum_{h \in \mathbb{Z}} \|\gamma_X(h)\|$ is convergent, then the *spectral density* of the series X_t can be defined by exactly the same formula as before:

$$f_X(\lambda) = \frac{1}{2\pi} \sum_{h \in \mathbb{Z}} \gamma_X(h) e^{-ih\lambda}.$$

The summation is now understood to be entry-wise, and hence $\lambda \mapsto f_X(\lambda)$ maps the interval $(-\pi, \pi]$ into the set of $(d \times d)$ -matrices, for d the dimension of the series X_t . Because the covariance function of the univariate series $\alpha^T X_t$ is given by $\gamma_{\alpha^T X} = \alpha^T \gamma_X \bar{\alpha}$, it follows that, for every $\alpha \in \mathbb{C}^d$,

$$\alpha^T f_X(\lambda) \bar{\alpha} = f_{\alpha^T X}(\lambda).$$

In particular, the matrix $f_X(\lambda)$ is nonnegative-definite, for every λ . From the identity $\gamma_X(-h)^T = \bar{\gamma_X}(h)$ it can also be ascertained that it is Hermitian: $f_X(\lambda)^T = \overline{f_X(\lambda)}$. The diagonal elements are nonnegative, but the off-diagonal elements of $f_X(\lambda)$ are complex valued, in general. If the time series X_t is real, then the spectral density is also conjugate symmetric: $f_X(-\lambda) = \overline{f_X(\lambda)}$, for every λ .

Warning. The spectral density is Hermitian. The autocovariance function is not.

As in the case of univariate time series, not every vector-valued time series possesses a spectral density, but every such series does possess a spectral distribution. This “distribution” is a matrix-valued, complex measure. A *complex Borel measure* on $(-\pi, \pi]$ is a map $B \mapsto F(B)$ on the Borel sets that can be written as $F = F_1 - F_2 + i(F_3 - F_4)$ for finite Borel measures F_1, F_2, F_3, F_4 . If the complex part $F_3 - F_4$ is identically zero, then F is a *signed measure*. The spectral measure F_X of a d -dimensional time series X_t is a $(d \times d)$ matrix whose d^2 entries are complex Borel measures on $(-\pi, \pi]$. The diagonal elements are precisely the spectral measures of the coordinate time series and hence are ordinary measures, but the off-diagonal measures are typically signed or complex measures. The measure F_X is *Hermitian* in the sense that $F_X(B)^T = \overline{F_X(B)}$ for every Borel set B .

6.38 Theorem (Herglotz). *For every stationary vector-valued time series X_t there exists a unique Hermitian-matrix-valued complex measure F_X on $(-\pi, \pi]$ such that*

$$\gamma_X(h) = \int_{(-\pi, \pi]} e^{ih\lambda} dF_X(\lambda), \quad h \in \mathbb{Z}.$$

Proof. For every $\alpha \in \mathbb{C}^d$ the time series $\alpha^T X_t$ is univariate and possesses a spectral measure $F_{\alpha^T X}$. By Theorem 6.2, for every $h \in \mathbb{Z}$,

$$\alpha^T \gamma_X(h) \bar{\alpha} = \gamma_{\alpha^T X}(h) = \int_{(-\pi, \pi]} e^{ih\lambda} dF_{\alpha^T X}(\lambda).$$

We can express any entry of the matrix $\gamma_X(h)$ as a linear combination of the quadratic form on the left side, evaluated for different vectors α . One possibility is to write, with e_k the k th unit vector in \mathbb{C}^d ,

$$\begin{aligned} 2\gamma_X(h)_{k,l} &= (e_k + e_l)^T \gamma_X(h) (e_k + e_l) + i(e_k + ie_l)^T \gamma_X(h) (e_k - ie_l) + \\ &\quad - (1 + i)(e_k^T \gamma_X(h) e_k + e_l^T \gamma_X(h) e_l). \end{aligned}$$

By expressing the right-hand side in the spectral matrices $F_{\alpha^T X}$, by using the first display, we obtain a representation $\gamma_X(h)_{k,l} = \int e^{ih\lambda} dF_{k,l}(\lambda)$, for a certain complex-valued measure $F_{k,l}$, for every (k, l) . Then the matrix-valued complex measure $F = (F_{k,l})$ satisfies $\gamma_X(h) = \int_{(-\pi, \pi]} e^{ih\lambda} dF(\lambda)$ and hence, for every $h \in \mathbb{Z}$,

$$\int_{(-\pi, \pi]} e^{ih\lambda} d\bar{F}^T(\lambda) = \overline{\gamma_X(-h)}^T = \gamma_X(h).$$

Thus the matrix-valued complex measure $F + \bar{F}^T$, which is Hermitian, also represents the autocovariance function.

If F is any Hermitian-matrix-valued complex measure with the representing property, then $\alpha^T F \bar{\alpha}$ must be the spectral measure of the time series $\alpha^T X_t$ and hence is uniquely determined. This determines $\alpha^T F(B) \bar{\alpha}$ for every $\alpha \in \mathbb{C}^d$, and therefore the Hermitian matrix $F(B)$, for every Borel set B . ■

Consider in particular a bivariate time series, written as $(X_t, Y_t)^T$ for univariate time series X_t and Y_t . The spectral density of (X_t, Y_t) , if it exists, is a (2×2) -matrix valued function. The diagonal elements are the spectral densities f_X and f_Y of the univariate series X_t and Y_t . The off-diagonal elements are complex conjugates and thus define one function, say f_{XY} for the $(1, 2)$ -element of the matrix, giving

$$f_{(X,Y)^T}(\lambda) = \begin{pmatrix} f_X(\lambda) & f_{XY}(\lambda) \\ \bar{f}_{XY}(\lambda) & f_Y(\lambda) \end{pmatrix}.$$

The following derived functions are often plotted:

$\operatorname{Re} f_{XY},$	<i>co-spectrum,</i>
$\operatorname{Im} f_{XY},$	<i>quadrature,</i>
$\frac{ f_{XY} ^2}{f_X f_Y},$	<i>coherency,</i>
$ f_{XY} ,$	<i>amplitude,</i>
$\arg f_{XY},$	<i>phase.</i>

It requires some experience to read the plots of these functions appropriately. The coherency is perhaps the easiest to interpret: evaluated at $\lambda \in (-\pi, \pi]$ it gives the “correlation between the series X and Y at the frequency λ ”.

6.39 EXERCISE. Show that the stationary time series X_t and Y_t are totally uncorrelated (i.e. $\operatorname{cov}(X_s, Y_t) = 0$ for every s and t) if and only if the spectral measure of the vector-valued process $(X_t, Y_t)^T$ is the product of the spectral measures F_X and F_Y of X and Y . What does this imply for the measure F_{XY} , the coherency, amplitude and phase?

A given sequence of $(d \times d)$ matrices ψ_j with $\sum_j \|\psi_j\| < \infty$ defines a *multivariate linear filter* that transforms a given d -dimensional time series X_t into the time series $Y_t = \sum_j \psi_j X_{t-j}$. The corresponding *multivariate transfer function* is the matrix-valued function $\lambda \mapsto \psi(\lambda) := \sum_j \psi_j e^{-ij\lambda}$. It plays the same role as the one-dimensional transfer function given in Theorem 6.11, whose proof goes through almost without changes.

6.40 Theorem. Let X_t be a multivariate stationary time series with spectral measure F_X and let $\sum_j \|\psi_j\| < \infty$. Then $Y_t = \sum_j \psi_j X_{t-j}$ has spectral measure F_Y given by

$$dF_Y(\lambda) = \psi(\lambda) dF_X(\lambda) \overline{\psi(\lambda)}^T.$$

The right side of the display is to be understood as a product of three matrices. If the series X_t possesses a spectral density f_X , then the right side is understood to be the matrix-valued measure with spectral density $\psi f_X \overline{\psi}^T$. In the general case the display means to express a relationship between the spectral measures F_Y and F_X , with the notations dF_Y and dF_X being only formal identifiers. One way of making the relation precise is to use some density \tilde{f}_X of F_X relative to some scalar measure $\tilde{\lambda}$ (not necessarily Lebesgue measure). Then F_Y possesses density $\psi \tilde{f}_X \overline{\psi}^T$ relative to the same dominating measure.

The spectral decomposition also extends to vector-valued time series. In particular, for a bivariate time series $(X_t, Y_t)^T$ there exist versions Z_X and Z_Y of their spectral measures (i.e. $X_t = \int e^{it\lambda} dZ_X(\lambda)$ and $Y_t = \int e^{it\lambda} dZ_Y(\lambda)$) such that, for pair of every measurable sets $B_1, B_2 \subset (-\pi, \pi]$,

$$\operatorname{cov}(Z_X(B_1), Z_Y(B_2)) = F_{X,Y}(B_1 \cap B_2).$$

* 6.6 Prediction in the Frequency Domain

As the spectrum encodes the complete second order structure of a stationary time series, it can be used to solve the (linear) prediction problem. The observed variables X_1, \dots, X_n are represented by the functions e_1, \dots, e_n , given by $e_h(\lambda) = e^{ih\lambda}$, in the spectral domain. A random variable Y in the closed linear span $L_2(X_t: t \in \mathbb{Z})$ of the time series can be represented as $Y = \int f dZ_X$ for some function $f \in L_2(F_X)$. By the spectral isometry,

$$\mathbb{E} \left| Y - \sum_{t=1}^n \alpha_t X_t \right|^2 = \int \left| f - \sum_{t=1}^n \alpha_t e_t \right|^2 dF_X.$$

Thus finding the best linear predictor of Y is the same as projecting f onto the linear span of e_1, \dots, e_n in $L_2(F_X)$.

If Y is not contained in $L_2(X_t: t \in \mathbb{Z})$, then we apply this argument to its projection onto this space, the orthogonal part of it being completely unpredictable.

The projection can be computed by solving the orthogonality relationship of Theorem 2.11. It is specific to the spectral measure F_X . Only in the special case that this is proportional to the uniform measure, this problem reduces to the usual one in Fourier analysis (and the truncated Fourier series gives an upper bound on the prediction error).

7

Law of Large Numbers

The law of large numbers is concerned with the convergence of the sequence \bar{X}_n of averages to its mean value. For statistical applications, the central limit theorem is of more interest, as it gives also expression to the size of the error when estimating the mean by the sample average. In fact, the central limit theorem implies the law of large numbers, as, by Slutsky's lemma $\bar{X}_n \rightarrow \mu$ in probability if the sequence $\sqrt{n}(\bar{X}_n - \mu)$ is uniformly tight. However, the law of large numbers is valid under much weaker conditions. The weakening not only concerns moments, but also the dependence between the X_t .

We present separate laws of large numbers for second order stationary and for strictly stationary sequences, respectively. The weak law for second order stationary time series can be fully characterized using the spectrum of the time series. The strong law of large numbers for a strictly stationary time series is a central result of *ergodic theory*. Actually both results show that the sequence \bar{X}_n always converges to a limit. However, in general this limit may be random. For nonstationary time series mixing conditions give alternative criteria.

* 7.1 Stationary Sequences

A mean zero, stationary time series X_t can be expressed in its spectral random measure Z_X through $X_t = \int e^{it\lambda} dZ_X(\lambda)$. (See Section 6.4.) A simple calculation then gives the following law of large numbers.

7.1 Theorem. *If X_t is a mean zero, stationary time series, then $\bar{X}_n \rightarrow Z_X\{0\}$ in second mean, as $n \rightarrow \infty$. In particular, if $F_X\{0\} = 0$, then $\bar{X}_n \xrightarrow{P} 0$.*

Proof. For Z_X the spectral measure of X , we write

$$\bar{X}_n = \frac{1}{n} \sum_{t=1}^n \int e^{it\lambda} dZ_X(\lambda) = \int \frac{e^{i\lambda}(1 - e^{i\lambda n})}{n(1 - e^{i\lambda})} dZ_X(\lambda).$$

Here the integrand must be read as 1 if $\lambda = 0$. For all other $\lambda \in (-\pi, \pi]$ the integrand converges to zero as $n \rightarrow \infty$. It is bounded by 1 for every λ . Hence the integrand converges in second mean to $1_{\{0\}}$ in $L_2(F_X)$. By the continuity of the integral $f \mapsto \int f dZ_X$, we find that \bar{X}_n converges in $L_2(\Omega, \mathcal{U}, P)$ to $\int 1_{\{0\}} dZ_X = Z_X\{0\}$.

The mean of the variable $Z_X\{0\}$ is zero, and its variance is equal to $F_X\{0\}$. If the latter is zero, then $Z_X\{0\}$ is degenerate at zero. ■

7.2 Ergodic Theorem

Given a strictly stationary sequence X_t , defined on some probability space (Ω, \mathcal{U}, P) and taking values in some measurable space $(\mathcal{X}, \mathcal{A})$, the *invariant σ -field*, denoted \mathcal{U}_{inv} , is the σ -field consisting of all sets A such that $A = (\dots, X_{t-1}, X_t, X_{t+1}, \dots)^{-1}(B)$ for all t and some measurable set $B \subset \mathcal{X}^\infty$. Here throughout this section the product space \mathcal{X}^∞ is equipped with the product σ -field \mathcal{A}^∞ .

Our notation in the definition of the invariant σ -field is awkward, if not unclear, because we look at two-sided infinite series. The triple X_{t-1}, X_t, X_{t+1} in the definition of A is meant to be centered at a fixed position in \mathbb{Z} . We can write this down more precisely using the *forward shift* function $S: \mathcal{X}^\infty \rightarrow \mathcal{X}^\infty$ defined by $S(x)_i = x_{i+1}$. The two-sided sequence $(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$ defines a map $X: \Omega \rightarrow \mathcal{X}^\infty$. The invariant sets A are the sets such that $A = \{S^t X \in B\}$ for all t and some measurable set $B \subset \mathcal{X}^\infty$. The strict stationarity of the sequence X is identical to the invariance of its induced law P^X on \mathcal{X}^∞ under the shift S .

The inverse images $X^{-1}(B)$ of measurable sets $B \subset \mathcal{X}^\infty$ with $B = SB$ are clearly invariant. Conversely, it can be shown that, up to null sets, all invariant sets take this form. (See Exercise 7.3.) The *symmetric events* are special examples of invariant sets. They are the events that depend symmetrically on the variables X_t . For instance, $\cap_t X_t^{-1}(B)$ for some measurable set $B \subset \mathcal{X}$.

* **7.2 EXERCISE.** Call a set $B \subset \mathcal{X}^\infty$ invariant under the shift $S: \mathcal{X}^\infty \rightarrow \mathcal{X}^\infty$ if $B = SB$. Call it *almost invariant* relative to a measure P^X if $P^X(B \triangle SB) = 0$. Show that a set B is almost invariant if and only if there exists an invariant set \tilde{B} such that $P^X(B \triangle \tilde{B}) = 0$. [Try $\tilde{B} = \cap_t S^t B$.]

* **7.3 EXERCISE.** Define the invariant σ -field \mathcal{B}_{inv} on \mathcal{X}^∞ as the collection of measurable sets that are invariant under the shift operation, and let $\overline{\mathcal{B}_{\text{inv}}}$ be its completion under the measure P^X . Show that $X^{-1}(\mathcal{B}_{\text{inv}}) \subset \mathcal{U}_{\text{inv}} \subset X^{-1}(\overline{\mathcal{B}_{\text{inv}}})$, where the long bar on the right denotes completion relative to P . [Note that $\{X \in B\} = \{X \in SB\}$ implies that $P^X(B \triangle SB) = 0$. Use the preceding exercise to replace B by an invariant set \tilde{B} .]

7.4 Theorem (Birkhoff). If X_t is a strictly stationary time series with $E|X_t| < \infty$, then $\bar{X}_n \rightarrow E(X_0 | \mathcal{U}_{\text{inv}})$ almost surely and in mean.

Proof. For a given $\alpha \in \mathbb{R}$ define a set $B = \{x \in \mathbb{R}^\infty : \limsup_{n \rightarrow \infty} \bar{x}_n > \alpha\}$. Because

$$\bar{x}_{n+1} = \frac{x_1}{n+1} + \frac{n}{n+1} \frac{1}{n} \sum_{t=2}^{n+1} x_t,$$

a point x is contained in B if and only if $\limsup_{n \rightarrow \infty} n^{-1} \sum_{t=2}^{n+1} x_t > \alpha$. Equivalently, $x \in B$ if and only if $Sx \in B$. Thus the set B is invariant under the shift operation $S: \mathbb{R}^\infty \rightarrow \mathbb{R}^\infty$. We conclude from this that the variable $\limsup_{n \rightarrow \infty} \bar{X}_n$ is measurable relative to the invariant σ -field.

Fix some measurable set $B \subset \mathbb{R}^\infty$. For every invariant set $A \in \mathcal{U}_{\text{inv}}$ there exists a measurable set $C \subset \mathbb{R}^\infty$ such that $A = \{S^t X \in C\}$ for every t . By the strict stationarity of X ,

$$P(\{S^t X \in B\} \cap A) = P(S^t X \in B, S^t X \in C) = P(X \in B, X \in C) = P(\{X \in B\} \cap A).$$

This shows that $P(S^t X \in B | \mathcal{U}_{\text{inv}}) = P(X \in B | \mathcal{U}_{\text{inv}})$ almost surely. We conclude that the conditional laws of $S^t X$ and X given the invariant σ -field are identical.

In particular, the conditional means $E(X_t | \mathcal{U}_{\text{inv}}) = E(X_1 | \mathcal{U}_{\text{inv}})$ are identical for every t , almost surely. It also follows that a time series Z_t of the type $Z_t = (X_t, R)$ for $R: \Omega \rightarrow \mathcal{R}$ a fixed \mathcal{U}_{inv} -measurable variable (for instance with values in $\mathcal{R} = \mathbb{R}^2$) is strictly stationary, the conditional law $B \mapsto P(X \in B | R) = E(P(X \in B | \mathcal{U}_{\text{inv}}) | R)$ of its first marginal (on \mathcal{X}^∞) being strictly stationary by the preceding paragraph, and the second marginal (on \mathcal{R}^∞) being independent of t .

For the almost sure convergence of the sequence \bar{X}_n it suffices to show that, for every $\varepsilon > 0$, the event

$$A = \left\{ \limsup_{n \rightarrow \infty} \bar{X}_n > E(X_1 | \mathcal{U}_{\text{inv}}) + \varepsilon \right\}$$

and a corresponding event for the lower tail have probability zero. By the preceding the event A is contained in the invariant σ -field. Furthermore, the time series $Y_t = (X_t - E(X_1 | \mathcal{U}_{\text{inv}}) - \varepsilon)1_A$, being a fixed transformation of the time series $Z_t = (X_t, E(X_1 | \mathcal{U}_{\text{inv}}), 1_A)$, is strictly stationary. We can write $A = \cup_n A_n$ for $A_n = \cup_{t=1}^n \{\bar{Y}_t > 0\}$. Then $EY_1 1_{A_n} \rightarrow EY_1 1_A$ by the dominated convergence theorem, in view of the assumption that X_t is integrable. If we can show that $EY_1 1_{A_n} \geq 0$ for every n , then we can conclude that

$$0 \leq EY_1 1_A = E(X_1 - E(X_1 | \mathcal{U}_{\text{inv}}))1_A - \varepsilon P(A) = -\varepsilon P(A),$$

because $A \in \mathcal{U}_{\text{inv}}$. This implies that $P(A) = 0$, concluding the proof of almost sure convergence.

The L_1 -convergence can next be proved by a truncation argument. We can first show, more generally, but by an identical argument, that $n^{-1} \sum_{t=1}^n f(X_t) \rightarrow E(f(X_0) | \mathcal{U}_{\text{inv}})$ almost surely, for every measurable function $f: \mathcal{X} \rightarrow \mathbb{R}$ with $E|f(X_t)| < \infty$. We can apply this to the functions $f(x) = x1_{|x| \leq M}$ for given M .

We complete the proof by showing that $EY_1 1_{A_n} \geq 0$ for every strictly stationary time series Y_t and every fixed n , and $A_n = \cup_{t=1}^n \{\bar{Y}_t > 0\}$. For every $2 \leq j \leq n$,

$$Y_1 + \cdots + Y_j \leq Y_1 + \max(Y_2, Y_2 + Y_3, \dots, Y_2 + \cdots + Y_{n+1}).$$

If we add the number 0 in the maximum on the right, then this is also true for $j = 1$. We can rewrite the resulting n inequalities as the single inequality

$$Y_1 \geq \max(Y_1, Y_1 + Y_2, \dots, Y_1 + \cdots + Y_n) - \max(0, Y_2, Y_2 + Y_3, \dots, Y_2 + \cdots + Y_{n+1}).$$

The event A_n is precisely the event that the first of the two maxima on the right is positive. Thus on this event the inequality remains true if we add also a zero to the first maximum. It follows that $EY_1 1_{A_n}$ is bounded below by

$$E\left(\max(0, Y_1, Y_1 + Y_2, \dots, Y_1 + \cdots + Y_n) - \max(0, Y_2, Y_2 + Y_3, \dots, Y_2 + \cdots + Y_{n+1})\right) 1_{A_n}.$$

Off the event A_n the first maximum is zero, whereas the second maximum is always nonnegative. Thus the expression does not increase if we cancel the indicator 1_{A_n} . The resulting expression is identically zero by the strict stationarity of the series Y_t . ■

Thus a strong law is valid for every integrable strictly stationary sequence, without any further conditions on possible dependence of the variables. However, the limit $E(X_0 | \mathcal{U}_{\text{inv}})$ in the preceding theorem will often be a true random variable. Only if the invariant σ -field is trivial, we can be sure that the limit is degenerate. Here “trivial” may be taken to mean that the invariant σ -field consists of sets of probability 0 or 1 only. If this is the case, then the time series X_t is called *ergodic*.

* **7.5 EXERCISE.** Suppose that X_t is strictly stationary. Show that X_t is ergodic if and only if every sequence $Y_t = f(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$ for a measurable map f that is integrable satisfies the law of large numbers $\bar{Y}_n \rightarrow EY_1$ almost surely. [Given an invariant set $A = (\dots, X_{-1}, X_0, X_1, \dots)^{-1}(B)$ consider $Y_t = 1_B(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$. Then $\bar{Y}_n = 1_A$.]

Checking that the invariant σ -field is trivial may be a nontrivial operation. There are other concepts that imply ergodicity and may be easier to verify. A time series X_t is called *mixing* if, for any measurable sets A and B , as $h \rightarrow \infty$,

$$\begin{aligned} &P((\dots, X_{h-1}, X_h, X_{h+1}, \dots) \in A, (\dots, X_{-1}, X_0, X_1, \dots) \in B) \\ &\quad - P((\dots, X_{h-1}, X_h, X_{h+1}, \dots) \in A)P((\dots, X_{-1}, X_0, X_1, \dots) \in B) \rightarrow 0. \end{aligned}$$

Every mixing time series is ergodic. This follows because if we take $A = B$ equal to an invariant set, the preceding display reads $P^X(A) - P^X(A)P^X(A) \rightarrow 0$, for P^X the law of the infinite series X_t , and hence $P^X(A)$ is 0 or 1.

The present type of mixing is related to the mixing concepts used to obtain central limit theorems, and is weaker.

7.6 Theorem. *Any strictly stationary α -mixing time series is mixing.*

Proof. For t -dimensional cylinder sets A and B in \mathcal{X}^∞ (i.e. sets that depend on finitely many coordinates only) the mixing condition becomes

$$P((X_h, \dots, X_{t+h}) \in A, (X_0, \dots, X_t) \in B) \rightarrow P((X_h, \dots, X_{t+h}) \in A)P((X_0, \dots, X_t) \in B).$$

For $h > t$ the absolute value of the difference of the two sides of the display is bounded by $\alpha(h - t)$ and hence converges to zero as $h \rightarrow \infty$, for each fixed t .

Thus the mixing condition is satisfied by the collection of all cylinder sets. This collection is intersection-stable, i.e. a π -system, and generates the product σ -field on \mathcal{X}^∞ . The proof is complete if we can show that the collections of sets A and B for which the mixing condition holds, for a given set B or A , is a σ -field. By the π - λ theorem it suffices to show that these collections of sets are a λ -system.

The mixing property can be written as $P^X(S^{-h}A \cap B) - P^X(A)P^X(B) \rightarrow 0$, as $h \rightarrow \infty$. Because S is a bijection we have $S^{-h}(A_2 - A_1) = S^{-h}A_2 - S^{-h}A_1$. If $A_1 \subset A_2$, then

$$\begin{aligned} P^X(S^{-h}(A_2 - A_1) \cap B) &= P^X(S^{-h}A_2 \cap B) - P^X(S^{-h}A_1 \cap B), \\ P^X(A_2 - A_1)P^X(B) &= P^X(A_2)P^X(B) - P^X(A_1)P^X(B). \end{aligned}$$

If, for a given set B , the sets A_1 and A_2 satisfy the mixing condition, then the right hand sides are asymptotically the same, as $h \rightarrow \infty$, and hence so are the left sides. Thus $A_2 - A_1$ satisfies the mixing condition. If $A_n \uparrow A$, then $S^{-h}A_n \uparrow S^{-h}A$ as $n \rightarrow \infty$ and hence

$$P^X(S^{-h}A_n \cap B) - P^X(A_n)P^X(B) \rightarrow P^X(S^{-h}A \cap B) - P^X(A)P^X(B).$$

The absolute difference of left and right sides is bounded above by $2|P^X(A_n) - P^X(A)|$. Hence the convergence in the display is uniform in h . If every of the sets A_n satisfies the mixing condition, for a given set B , then so does A . Thus the collection of all sets A that satisfies the condition, for a given B , is a λ -system.

We can prove similarly, but more easily, that the collection of all sets B is also a λ -system. ■

7.7 Theorem. *Any strictly stationary time series X_t with trivial tail σ -field is mixing.*

Proof. The tail σ -field is defined as $\cap_{h \in \mathbb{Z}} \sigma(X_h, X_{h+1}, \dots)$.

As in the proof of the preceding theorem we need to verify the mixing condition only for finite cylinder sets A and B . We can write

$$\begin{aligned} & \left| E 1_{X_h, \dots, X_{t+h} \in A} (1_{X_0, \dots, X_t \in B} - P(X_0, \dots, X_t \in B)) \right| \\ &= \left| E 1_{X_h, \dots, X_{t+h} \in A} (P(X_0, \dots, X_t \in B | X_h, X_{h+1}, \dots) - P(X_0, \dots, X_t \in B)) \right| \\ &\leq E \left| P(X_0, \dots, X_t \in B | X_h, X_{h+1}, \dots) - P(X_0, \dots, X_t \in B) \right|. \end{aligned}$$

For every integrable variable Y the sequence $E(Y | X_h, X_{h+1}, \dots)$ converges in L_1 to the conditional expectation of Y given the tail σ -field, as $h \rightarrow \infty$. Because the tail σ -field

is trivial, in the present case this is EY. Thus the right side of the preceding display converges to zero as $h \rightarrow \infty$. ■

- * **7.8 EXERCISE.** Show that a strictly stationary time series X_t is ergodic if and only if $n^{-1} \sum_{h=1}^n P^X(S^{-h}A \cap B) \rightarrow P^X(A)P^X(B)$, as $n \rightarrow \infty$, for every measurable subsets A and B of \mathcal{X}^∞ . [Use the ergodic theorem on the stationary time series $Y_t = 1_{S^t X \in A}$ to see that $n^{-1} \sum 1_{X \in S^{-t}A} 1_B \rightarrow P^X(A)1_B$ for the proof in one direction.]
- * **7.9 EXERCISE.** Show that a strictly stationary time series X_t is ergodic if and only if the one-sided time series X_0, X_1, X_2, \dots is ergodic, in the sense that the “one-sided invariant σ -field”, consisting of all sets A such that $A = (X_t, X_{t+1}, \dots)^{-1}(B)$ for some measurable set B and every $t \geq 0$, is trivial. [Use the preceding exercise.]

The preceding theorems can be used as starting points to construct ergodic sequences. For instance, every i.i.d. sequence is ergodic by the preceding theorems, because its tail σ -field is trivial by Kolmogorov’s 0-1 law, or because it is α -mixing. To construct more examples we can combine the theorems with the following stability property. From a given ergodic sequence X_t we construct a process Y_t by transforming the vector $(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$ with a given map f from the product space \mathcal{X}^∞ into some measurable space $(\mathcal{Y}, \mathcal{B})$. As before, the X_t in $(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$ is meant to be at a fixed 0th position in \mathbb{Z} , so that the different variables Y_t are obtained by sliding the function f along the sequence $(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$.

7.10 Theorem. *The sequence $Y_t = f(\dots, X_{t-1}, X_t, X_{t+1}, \dots)$ obtained by application of a measurable map $f: \mathcal{X}^\infty \rightarrow \mathcal{Y}$ to an ergodic sequence X_t is ergodic.*

Proof. Define $\bar{f}: \mathcal{X}^\infty \rightarrow \mathcal{Y}^\infty$ by $\bar{f}(x) = (\dots, f(S^{-1}x), f(x), f(Sx), \dots)$, for S the forward shift on \mathcal{X}^∞ . Then $Y = \bar{f}(X)$ and $S' \bar{f}(x) = \bar{f}(Sx)$, if S' is the forward shift on \mathcal{Y}^∞ . Consequently $(S')^t Y = \bar{f}(S^t X)$. If $A = \{(S')^t Y \in B\}$ is invariant for the series Y_t , then $A = \{\bar{f}(S^t X) \in B\} = \{S^t X \in \bar{f}^{-1}(B)\}$ for every t , and hence A is also invariant for the series X_t . ■

7.11 EXERCISE. Let Z_t be an i.i.d. sequence of integrable variables and let $X_t = \sum_j \psi_j Z_{t-j}$ for a sequence ψ_j such that $\sum_j |\psi_j| < \infty$. Show that X_t satisfies the law of large numbers (with degenerate limit).

7.12 EXERCISE. Show that the GARCH(1,1) process defined in Example 1.10 is ergodic.

7.13 Example (Discrete Markov chains). Every stationary irreducible Markov chain on a countable state space is ergodic. Conversely, a stationary reducible Markov chain on a countable state space whose initial (or marginal) law is positive everywhere is nonergodic.

To prove the ergodicity note that a stationary irreducible Markov chain is (positively) recurrent (e.g. Durrett, p266). If A is an invariant set of the form $A = (X_0, X_1, \dots)^{-1}(B)$, then $A \in \sigma(X_h, X_{h-1}, \dots)$ for all h and hence

$$\begin{aligned} 1_A &= P(A | X_h, X_{h-1}, \dots) = P((X_{h+1}, X_{h+2}, \dots) \in B | X_h, X_{h-1}, \dots) \\ &= P((X_{h+1}, X_{h+2}, \dots) \in B | X_h). \end{aligned}$$

We can write the right side as $g(X_h)$ for the function $g(x) = P(A | X_{-1} = x)$. By recurrence, for almost every ω in the underlying probability space, the right side runs infinitely often through every of the numbers $g(x)$ with x in the state space. Because the left side is 0 or 1 for a fixed ω , the function g and hence 1_A must be constant. Thus every invariant set of this type is trivial, showing the ergodicity of the one-sided sequence X_0, X_1, \dots . It can be shown that one-sided and two-sided ergodicity are the same. (Cf. Exercise 7.9.)

Conversely, if the Markov chain is reducible, then the state space can be split into two sets \mathcal{X}_1 and \mathcal{X}_2 such that the chain will remain in \mathcal{X}_1 or \mathcal{X}_2 once it enters there. If the initial distribution puts positive mass everywhere, then each of the two possibilities occurs with positive probability. The sets $A_i = \{X_0 \in \mathcal{X}_i\}$ are then invariant and nontrivial and hence the chain is not ergodic.

It can also be shown that a stationary irreducible Markov chain is mixing if and only if it is aperiodic. (See e.g. Durrett, p310.) Furthermore, the tail σ -field of any irreducible stationary aperiodic Markov chain is trivial. (See e.g. Durrett, p279.) \square

7.3 Mixing

In the preceding section it was seen that an α -mixing, strictly stationary time series is ergodic and hence satisfies the law of large numbers if it is integrable. In this section we extend the law of large numbers to possibly nonstationary α -mixing time series.

The key is the bound on the tails of the distribution of the sample mean given in the following lemma.

7.14 Lemma. *For any mean zero time series X_t with α -mixing numbers $\alpha(h)$, every $x > 0$ and every $h \in \mathbb{N}$, with $Q_t = F_{|X_t|}^{-1}$,*

$$P(\bar{X}_n \geq 2x) \leq \frac{2}{nx^2} \int_0^1 (\alpha^{-1}(u) \wedge h) \frac{1}{n} \sum_{t=1}^n Q_t^2(1-u) du + \frac{2}{x} \int_0^{\alpha(h)} \frac{1}{n} \sum_{t=1}^n Q_t(1-u) du.$$

Proof. The quantile function of the variable $|X_t|/(xn)$ is equal to $u \mapsto F_{|X_t|}^{-1}(u)/(nx)$. Therefore, by a rescaling argument we can see that it suffices to bound the probability $P(\sum_{t=1}^n X_t \geq 2)$ by the right side of the lemma, but with the factors $2/(nx^2)$ and $2/x$ replaced by 2 and the factor n^{-1} in front of $\sum Q_t^2$ and $\sum Q_t$ dropped. For ease of notation set $S_0 = 0$ and $S_n = \sum_{t=1}^n X_t$.

Define the function $g: \mathbb{R} \rightarrow \mathbb{R}$ to be 0 on the interval $(-\infty, 0]$, to be $x \mapsto \frac{1}{2}x^2$ on $[0, 1]$, to be $x \mapsto 1 - \frac{1}{2}(x-2)^2$ on $[1, 2]$, and to be 1 on $[2, \infty)$. Then g is continuously differentiable with uniformly Lipschitz derivative. By Taylor's theorem it follows that $|g(x) - g(y) - g'(x)(x-y)| \leq \frac{1}{2}|x-y|^2$ for every $x, y \in \mathbb{R}$. Because $1_{[2, \infty)} \leq g$ and $S_t - S_{t-1} = X_t$,

$$P(S_n \geq 2) \leq Eg(S_n) = \sum_{t=1}^n E(g(S_t) - g(S_{t-1})) \leq \sum_{t=1}^n E|g'(S_{t-1})X_t| + \frac{1}{2} \sum_{t=1}^n EX_t^2.$$

The last term on the right can be written $\frac{1}{2} \sum_{t=1}^n \int_0^1 Q_t^2(1-u) du$, which is bounded by $\sum_{t=1}^n \int_0^{\alpha(0)} Q_t^2(1-u) du$, because $\alpha(0) = \frac{1}{2}$ and $u \mapsto Q_t(1-u)$ is decreasing.

For $i \geq 1$ the variable $g'(S_{t-i}) - g'(S_{t-i-1})$ is measurable relative to $\sigma(X_s: s \leq t-i)$ and is bounded in absolute value by $|X_{t-i}|$. Therefore, Lemma 4.12 yields the inequality

$$|E(g'(S_{t-i}) - g'(S_{t-i-1}))X_t| \leq 2 \int_0^{\alpha(i)} Q_{t-i}(1-u)Q_t(1-u) du.$$

For $t \leq h$ we can write $g'(S_{t-1}) = \sum_{i=1}^{t-1} (g'(S_{t-i}) - g'(S_{t-i-1}))$. Substituting this in the left side of the following display and applying the preceding display, we find that

$$\sum_{t=1}^h E|g'(S_{t-1})X_t| \leq 2 \sum_{t=1}^h \sum_{i=1}^{t-1} \int_0^{\alpha(i)} Q_{t-i}(1-u)Q_t(1-u) du.$$

For $t > h$ we can write $g'(S_{t-1}) = g'(S_{t-h}) + \sum_{i=1}^{h-1} (g'(S_{t-i}) - g'(S_{t-i-1}))$. By a similar argument, this time also using that the function $|g'|$ is uniformly bounded by 1, we find

$$\sum_{t=h+1}^n E|g'(S_{t-1})X_t| \leq 2 \int_0^{\alpha(h)} Q_t(1-u) du + 2 \sum_{t=h+1}^n \sum_{i=1}^{h-1} \int_0^{\alpha(i)} Q_{t-i}(1-u)Q_t(1-u) du.$$

Combining the preceding displays we obtain that $P(S_n \geq 2)$ is bounded above by

$$2 \int_0^{\alpha(h)} Q_t(1-u) du + 2 \sum_{t=1}^n \sum_{i=1}^{t \wedge h-1} \int_0^{\alpha(i)} Q_{t-i}(1-u)Q_t(1-u) du + \frac{1}{2} \sum_{t=1}^n EX_t^2.$$

In the second term we can bound $2Q_{t-i}(1-u)Q_t(1-u)$ by $Q_{t-i}^2(1-u) + Q_t^2(1-u)$ and next change the order of summation to $\sum_{i=1}^{h-1} \sum_{t=i+1}^n$. Because $\sum_{t=i+1}^n (Q_{t-i}^2 + Q_t^2) \leq 2 \sum_{t=1}^n Q_t^2$ this term is bounded by $2 \sum_{i=1}^{h-1} \int_0^{\alpha(i)} \sum_{t=1}^n Q_t^2(1-u) du$. Together with the third term on the right this gives rise to by the first sum on the right of the lemma, as $\sum_{i=0}^{h-1} 1_{u \leq \alpha(i)} = \alpha^{-1}(u) \wedge h$. ■

7.15 Theorem. For each n let the time series $(X_{n,t}: t \in \mathbb{Z})$ be mixing with mixing coefficients $\alpha_n(h)$. If $\sup_n \alpha_n(h) \rightarrow 0$ as $h \rightarrow \infty$ and $(X_{n,t}: t \in \mathbb{Z}, n \in \mathbb{N})$ is uniformly integrable, then the sequence $\bar{X}_n - E\bar{X}_n$ converges to zero in probability.

Proof. By the assumption of uniform integrability $n^{-1} \sum_{t=1}^n E|X_{n,t}|1_{|X_{n,t}| > M} \rightarrow 0$ as $M \rightarrow \infty$ uniformly in n . Therefore we can assume without loss of generality that $X_{n,t}$ is

bounded in absolute value by a constant M . We can also assume that it is centered at mean zero.

Then the quantile function of $|X_{n,t}|$ is bounded by M and the preceding lemma yields the bound

$$P(|\bar{X}_n| \geq 2\varepsilon) \leq \frac{4hM^2}{n\varepsilon^2} + \frac{4M}{\varepsilon} \sup_n \alpha_n(h).$$

This converges to zero as $n \rightarrow \infty$ followed by $h \rightarrow \infty$. ■

* **7.16 EXERCISE.** Relax the conditions in the preceding theorem to, for every $\varepsilon > 0$:

$$n^{-1} \sum_{t=1}^n E|X_{n,t}| 1_{|X_{n,t}| > \varepsilon n \wedge F_{|X_{n,t}|}^{-1}(1-\alpha_n(h))} \rightarrow 0.$$

[Hint: truncate at the level $n\varepsilon_n$ and note that $EX1_{X>M} = \int_0^1 Q(1-u)1_{Q(1-u)>M} du$ for $Q(u) = F_X^{-1}(u)$.]

7.4 Subadditive Ergodic Theorem

Kingman's subadditive theorem can be considered an extension of the ergodic theorem that gives the almost sure convergence of more general functions of a strictly stationary sequence than the consecutive means. Given a strictly stationary time series X_t with values in some measurable space $(\mathcal{X}, \mathcal{A})$ and defined on some probability space (Ω, \mathcal{U}, P) , write X for the induced map $(\dots, X_{-1}, X_0, X_1, \dots): \Omega \rightarrow \mathcal{X}^\infty$, and let $S: \mathcal{X}^\infty \rightarrow \mathcal{X}^\infty$ be the forward shift function (all as before). A family $(T_n: n \in \mathbb{N})$ of maps $T_n: \mathcal{X}^\infty \rightarrow \mathbb{R}$ is called *subadditive* if, for every $m, n \in \mathbb{N}$,

$$T_{m+n}(X) \leq T_m(X) + T_n(S^m X).$$

7.17 Theorem (Kingman). *If X is strictly stationary with invariant σ -field \mathcal{U}_{inv} and the maps $(T_n: n \in \mathbb{N})$ are subadditive with finite means $ET_n(X)$, then $T_n(X)/n \rightarrow \gamma := \inf_n n^{-1}E(T_n(X)|\mathcal{U}_{\text{inv}})$ almost surely. Furthermore, the limit γ satisfies $E\gamma > -\infty$ if and only if $\inf_n ET_n(X)/n > -\infty$ and in that case the convergence $T_n(X) \rightarrow \gamma$ takes also place in mean.*

Proof. See e.g. Dudley (1987), Theorem 10.7.1. ■

Because the maps $T_n(X) = \sum_{t=1}^n X_t$ are subadditive (in fact additive, with equality rather than inequality), the “ordinary” ergodic theorem by Birkhoff is a special case of Kingman's theorem. If the time series X_t is ergodic, then the limit γ in Kingman's theorem is equal to the number $\gamma = \inf_n n^{-1}ET_n(X)$ in $[-\infty, \infty)$.

7.18 EXERCISE. Show that the sequence of normalized means $n^{-1}ET_n(X)$ of a subadditive map tend to $\inf_n n^{-1}ET_n(X)$. [Hint: along the subsequence $n = 2^j$ they are decreasing.]

7.19 EXERCISE. Let X_t be a time series with values in the collection of $(d \times d)$ matrices. Show that the maps defined by $T_n(X) = \log \|X_{-1} \cdots X_{-n}\|$ are subadditive.

7.20 EXERCISE. Show that Kingman's theorem remains true if the forward shift operator in the definition of subadditivity is replaced by the backward shift operator. [Hint: If $R: \mathcal{X}^\infty \rightarrow \mathcal{X}^\infty$ is the reflection $(RX)_t = X_{-t}$, then $RS^m X = B^m RX$. Reverse time by considering $T_n(RX)$.]

8

ARIMA Processes

For many years ARIMA processes were the work horses of time series analysis, the “statistical analysis of time series” being almost identical to fitting an appropriate ARIMA process. This important class of time series models are defined through linear relations between the observations and noise factors.

8.1 Backshift Calculus

To simplify notation we define the *backshift operator* B through

$$BX_t = X_{t-1}, \quad B^k X_t = X_{t-k}.$$

This is viewed as operating on a complete time series X_t , transforming this into a new series by a time shift. Even though we use the word “operator”, we shall use B only as a notational device. In particular, $BY_t = Y_{t-1}$ for any other time series Y_t .[‡]

For a given polynomial $\psi(z) = \sum_j \psi_j z^j$ we also abbreviate

$$\psi(B)X_t = \sum_j \psi_j X_{t-j}.$$

If the series on the right is well defined, then we even use this notation for infinite *Laurent series* $\sum_{j=-\infty}^{\infty} \psi_j z^j$. Then $\psi(B)X_t$ is simply a short-hand notation for the (infinite) linear filters that we encountered before. By Lemma 1.29 the filtered time series $\psi(B)X_t$

[‡] Be aware of the dangers of this notation. For instance, if $Y_t = X_{-t}$, then $BY_t = Y_{t-1} = X_{-(t-1)}$. This is probably the intended meaning. We could also argue that $BY_t = BX_{-t} = X_{-t-1}$. This is something else. Such inconsistencies can be avoided by viewing B as acting on a full time series rather than individual variables; or alternatively by defining B as a true operator, for instance a linear operator acting on the linear span of a given time series. In the second case B may be different for different time series; e.g. the two given examples are resolved by writing $B_Y Y_t = Y_{t-1}$ and $B_X Y_t = B_X X_{-t} = X_{-t-1}$.

is certainly well defined if $\sum_j |\psi_j| < \infty$ and $\sup_t E|X_t| < \infty$, in which case the series converges both almost surely and in mean.

If $\sum_j |\psi_j| < \infty$, then the Laurent series $\sum_j \psi_j z^j$ converges absolutely on the unit circle $S^1 = \{z \in \mathbb{C}: |z| = 1\}$ in the complex plane and hence defines a function $\psi: S^1 \rightarrow \mathbb{C}$. In turn, the values of this function determine the coefficients. (See the next exercise.) Given two of such series or functions $\psi_1(z) = \sum_j \psi_{1,j} z^j$ and $\psi_2(z) = \sum_j \psi_{2,j} z^j$, the product $\psi(z) = \psi_1(z)\psi_2(z)$ is a well-defined function on (at least) the unit circle. By changing the summation indices (which is permitted in view of absolute convergence) this can be written as

$$\psi(z) = \psi_1(z)\psi_2(z) = \sum_j \psi_j z^j, \quad \psi_k = \sum_j \psi_{1,j} \psi_{2,k-j}.$$

The coefficients ψ_j are called the *convolutions* of the coefficients $\psi_{1,j}$ and $\psi_{2,j}$. Under the condition that $\sum_j |\psi_{i,j}| < \infty$ for $i = 1, 2$, the Laurent series $\sum_k \psi_k z^k$ converges absolutely at least on the unit circle: $\sum_k |\psi_k| < \infty$.

8.1 EXERCISE. Show that

- (i) If $\psi(z) = \sum_j \psi_j z^j$, for an absolutely summable sequence (ψ_j) , then $\psi_j = (2\pi i)^{-1} \int_{S^1} \psi(z) z^{-1-j} dz$.
- (ii) The convolution (ψ_j) of two sequences $(\psi_{i,j})$ of filter coefficients ($i = 1, 2$) satisfies $\sum_k |\psi_k| \leq \sum_j |\psi_{1,j}| \sum_j |\psi_{2,j}|$.

Having defined the function $\psi(z)$ and verified that it has an absolutely convergent Laurent series representation on the unit circle, we can now also define the time series $\psi(B)X_t$. The following lemma shows that the convolution formula remains valid if z is replaced by B , at least when applied to time series that are bounded in L_1 .

8.2 Lemma. *If both $\sum_j |\psi_{1,j}| < \infty$ and $\sum_j |\psi_{2,j}| < \infty$, then, for every time series X_t with $\sup_t E|X_t| < \infty$,*

$$\psi(B)X_t = \psi_1(B)[\psi_2(B)X_t], \quad \text{a.s..}$$

Proof. The right side is to be read as $\psi_1(B)Y_t$ for $Y_t = \psi_2(B)X_t$. The variable Y_t is well defined almost surely by Lemma 1.29, because $\sum_j |\psi_{2,j}| < \infty$ and $\sup_t E|X_t| < \infty$. Furthermore,

$$\sup_t E|Y_t| = \sup_t E \left| \sum_j \psi_{2,j} X_{t-j} \right| \leq \sum_j |\psi_{2,j}| \sup_t E|X_t| < \infty.$$

Thus the time series $\psi_1(B)Y_t$ is also well defined by Lemma 1.29. Now

$$E \sum_i \sum_j |\psi_{1,i}| |\psi_{2,j}| |X_{t-i-j}| \leq \sup_t E|X_t| \sum_i |\psi_{1,i}| \sum_j |\psi_{2,j}| < \infty.$$

This implies that the double series $\sum_i \sum_j \psi_{1,i} \psi_{2,j} X_{t-i-j}$ converges absolutely, and hence unconditionally, almost surely. The latter means that we may sum the terms in an arbitrary order. In particular, by the change of variables $(i, j) \mapsto (i = l, i + j = k)$,

$$\sum_i \psi_{1,i} \left(\sum_j \psi_{2,j} X_{t-i-j} \right) = \sum_k \left(\sum_l \psi_{1,l} \psi_{2,k-l} \right) X_{t-k}, \quad \text{a.s..}$$

This is the assertion of the lemma, with $\psi_1(B)[\psi_2(B)X_t]$ on the left side, and $\psi(B)X_t$ on the right. ■

The lemma implies that the “operators” $\psi_1(B)$ and $\psi_2(B)$ “commute”. From now on we omit the square brackets in $\psi_1(B)[\psi_2(B)X_t]$.

8.3 EXERCISE. Verify that the lemma remains valid for any sequences ψ_1 and ψ_2 with $\sum_j |\psi_{i,j}| < \infty$ and every process X_t such that $\sum_i \sum_j |\psi_{1,i}| |\psi_{2,j}| |X_{t-i-j}| < \infty$ almost surely. In particular, conclude that $\psi_1(B)\psi_2(B)X_t = (\psi_1\psi_2)(B)X_t$ for any polynomials ψ_1 and ψ_2 and every time series X_t .

8.2 ARMA Processes

Linear regression models attempt to explain a variable by the sum of a linear function of explanatory variables and a noise variable. ARMA processes are a time series version of linear regression, where the explanatory variables are the past values of the time series itself and the added noise is a moving average process.

8.4 Definition. A time series X_t is an $ARMA(p, q)$ -process if there exist polynomials ϕ and θ of degrees p and q , respectively, and a white noise series Z_t such that $\phi(B)X_t = \theta(B)Z_t$.

The equation $\phi(B)X_t = \theta(B)Z_t$ is to be understood as “pointwise almost surely” on the underlying probability space: the random variables X_t and Z_t are defined on a probability space (Ω, \mathcal{U}, P) and satisfy $\phi(B)X_t(\omega) = \theta(B)Z_t(\omega)$ for almost every $\omega \in \Omega$.

Warning. Some authors require by definition that an ARMA process be stationary. This is one way of making the solution to the ARMA equation unique. Some authors fail to recognize that the ARMA equation by itself does not *define* a unique process, without initialization or a side constraint. Many authors occasionally forget to say explicitly that they are concerned with a stationary ARMA process.

The polynomials are often[†] written in the forms $\phi(z) = 1 - \phi_1 z - \phi_2 z^2 - \cdots - \phi_p z^p$ and $\theta(z) = 1 + \theta_1 z + \cdots + \theta_q z^q$. Then the equation $\phi(B)X_t = \theta(B)Z_t$ takes the form

$$X_t = \phi_1 X_{t-1} + \phi_2 X_{t-2} + \cdots + \phi_p X_{t-p} + Z_t + \theta_1 Z_{t-1} + \cdots + \theta_q Z_{t-q}.$$

[†] A notable exception is the Splus package. Its makers appear to have overdone the cleverness of including minus-signs in the coefficients of ϕ and have included them in the coefficients of θ also.

In other words: the value of the time series X_t at time t is the sum of a linear regression on its own past and of a moving average. An $\text{ARMA}(p, 0)$ -process is also called an *auto-regressive process* and denoted $\text{AR}(p)$; an $\text{ARMA}(0, q)$ -process is also called a *moving average process* and denoted $\text{MA}(q)$. Thus an auto-regressive process is a solution X_t to the equation $\phi(B)X_t = Z_t$, and a moving average process is explicitly given by $X_t = \theta(B)Z_t$.

8.5 EXERCISE. Why is it not a loss of generality to assume $\phi_0 = \theta_0 = 1$?

We next investigate for which pairs of polynomials ϕ and θ there exists a corresponding *stationary* ARMA-process. For given polynomials ϕ and θ and a white noise series Z_t , there are always many time series X_t that satisfy the ARMA equation, but none of these may be stationary. If there exists a stationary solution, then we are also interested in knowing whether this is uniquely determined by the pair (ϕ, θ) and/or the white noise series Z_t , and in what way it depends on the series Z_t .

8.6 Example. The polynomial $\phi(z) = 1 - \phi z$ leads to the auto-regressive equation $X_t = \phi X_{t-1} + Z_t$. In Example 1.8 we have seen that a stationary solution exists if and only if $|\phi| \neq 1$. \square

8.7 EXERCISE. Let arbitrary polynomials ϕ and θ , a white noise sequence Z_t and variables X_1, \dots, X_p be given. Show that there exists a time series X_t that satisfies the equation $\phi(B)X_t = \theta(B)Z_t$ and coincides with the given X_1, \dots, X_p at times $1, \dots, p$. What does this imply about existence of solutions if only the Z_t and the polynomials ϕ and θ are given?

In the following theorem we shall see that a stationary solution to the ARMA-equation exists if the polynomial $z \mapsto \phi(z)$ has no roots on the unit circle $S^1 = \{z \in \mathbb{C}: |z| = 1\}$. To prove this, we need some facts from complex analysis. The function

$$\psi(z) = \frac{\theta(z)}{\phi(z)}$$

is well defined and analytic on the region $\{z \in \mathbb{C}: \phi(z) \neq 0\}$. If ϕ has no roots on the unit circle S^1 , then, since it has at most p different roots, there is an annulus $\{z: r < |z| < R\}$ with $r < 1 < R$ on which it has no roots. On this annulus ψ is an analytic function, and it has a *Laurent series* representation

$$\psi(z) = \sum_{j=-\infty}^{\infty} \psi_j z^j.$$

This series is uniformly and absolutely convergent on every compact subset of the annulus, and the coefficients ψ_j are uniquely determined by the values of ψ on the annulus. In particular, because the unit circle is inside the annulus, we obtain that $\sum_j |\psi_j| < \infty$.

Then we know from Lemma 1.29 that $\psi(B)Z_t$ is a well defined, stationary time series. By the following theorem it is the unique stationary solution to the ARMA-equation. Here the white noise series Z_t and the probability space on which it is defined are considered given. (In analogy with the terminology of stochastic analysis, the latter expresses that there exists a unique *strong solution*.)

8.8 Theorem. *Let ϕ and θ be polynomials such that ϕ has no roots on the complex unit circle, and let Z_t be a white noise process. Define $\psi = \theta/\phi$. Then $X_t = \psi(B)Z_t$ is the unique stationary solution to the equation $\phi(B)X_t = \theta(B)Z_t$. It is also the only solution that is bounded in L_1 .*

Proof. By the rules of calculus justified by Lemma 8.2, $\phi(B)\psi(B)Z_t = \theta(B)Z_t$, because $\phi(z)\psi(z) = \theta(z)$ on an annulus around the unit circle, the series $\sum_j |\phi_j|$ and $\sum_j |\psi_j|$ converge and the time series Z_t is bounded in absolute mean. This proves that $\psi(B)Z_t$ is a solution to the ARMA-equation. It is stationary by Lemma 1.29.

Let X_t be an arbitrary solution to the ARMA equation that is bounded in L_1 , for instance a stationary solution. The function $\tilde{\phi}(z) = 1/\phi(z)$ is analytic on an annulus around the unit circle and hence possesses a unique Laurent series representation $\tilde{\phi}(z) = \sum_j \tilde{\phi}_j z^j$. Because $\sum_j |\tilde{\phi}_j| < \infty$, the infinite series $\tilde{\phi}(B)Y_t$ is well defined for every stationary time series Y_t by Lemma 1.29. By the calculus of Lemma 8.2 $\tilde{\phi}(B)\phi(B)X_t = X_t$ almost surely, because $\tilde{\phi}(z)\phi(z) = 1$, the filter coefficients are summable and the time series X_t is bounded in absolute mean. Therefore, the equation $\phi(B)X_t = \theta(B)Z_t$ implies, after multiplying by $\tilde{\phi}(B)$, that $X_t = \tilde{\phi}(B)\theta(B)Z_t = \psi(B)Z_t$, again by the calculus of Lemma 8.2, because $\tilde{\phi}(z)\theta(z) = \psi(z)$. This proves that $\psi(B)Z_t$ is the unique stationary solution to the ARMA-equation. ■

8.9 EXERCISE. It is certainly not true that $\psi(B)Z_t$ is the only solution to the ARMA-equation. Can you trace where in the preceding proof we use the required stationarity of the solution? Would you agree that the “calculus” of Lemma 8.2 is perhaps more subtle than it appeared to be at first?

Thus the condition that ϕ has no roots on the unit circle is sufficient for the existence of a stationary solution. It is almost necessary. The only point is that it is really the quotient θ/ϕ that counts, not the function ϕ on its own. If ϕ has a zero on the unit circle of the same or smaller multiplicity as θ , then this quotient is still a nice function. Once this possibility is excluded, there can be no stationary solution if $\phi(z) = 0$ for some z with $|z| = 1$.

8.10 Theorem. *Let ϕ and θ be polynomials such that ϕ has a root on the unit circle that is not a root of θ , and let Z_t be a white noise process. Then there exists no stationary solution X_t to the equation $\phi(B)X_t = \theta(B)Z_t$.*

Proof. Suppose that the contrary is true and let X_t be a stationary solution. Then X_t has a spectral distribution F_X , and hence so does the time series $\phi(B)X_t = \theta(B)Z_t$. By

Theorem 6.11 and Example 6.6 we must have

$$|\phi(e^{-i\lambda})|^2 dF_X(\lambda) = |\theta(e^{-i\lambda})|^2 \frac{\sigma^2}{2\pi} d\lambda.$$

Now suppose that $\phi(e^{-i\lambda_0}) = 0$ and $\theta(e^{-i\lambda_0}) \neq 0$ for some $\lambda_0 \in (-\pi, \pi]$. The preceding display is just an equation between densities of measures and should not be interpreted as being valid for every λ , so we cannot immediately conclude that there is a contradiction. By differentiability of ϕ and continuity of θ there exist positive numbers A and B and a neighbourhood of λ_0 on which both $|\phi(e^{-i\lambda})| \leq A|\lambda - \lambda_0|$ and $|\theta(e^{-i\lambda})| \geq B$. Combining this with the preceding display, we see that, for all sufficiently small $\varepsilon > 0$,

$$\int_{\lambda_0 - \varepsilon}^{\lambda_0 + \varepsilon} A^2 |\lambda - \lambda_0|^2 dF_X(\lambda) \geq \int_{(\lambda_0 - \varepsilon) \wedge \pi}^{(\lambda_0 + \varepsilon) \vee (-\pi)} B^2 \frac{\sigma^2}{2\pi} d\lambda.$$

The left side is bounded above by $A^2 \varepsilon^2 F_X[\lambda_0 - \varepsilon, \lambda_0 + \varepsilon]$, whereas the right side is bounded below by $B^2 \sigma^2 \varepsilon / (2\pi)$, for small ε . This shows that $F_X[\lambda_0 - \varepsilon, \lambda_0 + \varepsilon] \rightarrow \infty$ as $\varepsilon \rightarrow 0$ and contradicts the fact that F_X is a finite measure. ■

8.11 Example. The AR(1)-equation $X_t = \phi X_{t-1} + Z_t$ corresponds to the polynomial $\phi(z) = 1 - \phi z$. This has root ϕ^{-1} . Therefore a stationary solution exists if and only if $|\phi^{-1}| \neq 1$. In the latter case, the Laurent series expansion of $\psi(z) = 1/(1 - \phi z)$ around the unit circle is given by $\psi(z) = \sum_{j=0}^{\infty} \phi^j z^j$ for $|\phi| < 1$ and is given by $-\sum_{j=1}^{\infty} \phi^{-j} z^{-j}$ for $|\phi| > 1$. Consequently, the unique stationary solutions in these cases are given by

$$X_t = \begin{cases} \sum_{j=0}^{\infty} \phi^j Z_{t-j}, & \text{if } |\phi| < 1, \\ -\sum_{j=1}^{\infty} \frac{1}{\phi^j} Z_{t+j}, & \text{if } |\phi| > 1. \end{cases}$$

This is in agreement, of course, with Example 1.8. □

8.12 EXERCISE. Investigate the existence of stationary solutions to:

- (i) $X_t = \frac{1}{2}X_{t-1} + \frac{1}{2}X_{t-2} + Z_t$;
- (ii) $X_t = \frac{1}{2}X_{t-1} + \frac{1}{4}X_{t-2} + Z_t + \frac{1}{2}Z_{t-1} + \frac{1}{4}Z_{t-2}$.

Warning. Some authors mistakenly believe that stationarity requires that ϕ has no roots inside the unit circle.

If given time series X_t and Z_t satisfy the ARMA-equation $\phi(B)X_t = \theta(B)Z_t$, then they also satisfy $r(B)\phi(B)X_t = r(B)\theta(B)Z_t$, for any polynomial r . From observed data X_t it is impossible to determine whether (ϕ, θ) or $(r\phi, r\theta)$ are the “right” polynomials. To avoid this problem of indeterminacy, we assume from now on that the ARMA-model is always written in its simplest form. This is when ϕ and θ do not have common factors (are relatively prime in the algebraic sense), or equivalently, when ϕ and θ do not have common (complex) roots. Then, in view of the preceding theorems, a stationary solution X_t to the ARMA-equation exists if and only if ϕ has no roots on the unit circle, and this is uniquely given by

$$X_t = \psi(B)Z_t = \sum_j \psi_j Z_{t-j}, \quad \psi = \frac{\theta}{\phi}.$$

8.13 Definition. An ARMA-process X_t is called *causal* if, in the preceding representation, the filter is causal: i.e. $\psi_j = 0$ for every $j < 0$.

Thus a causal ARMA-process X_t depends on the present and past values Z_t, Z_{t-1}, \dots of the noise sequence only. Intuitively, this is a desirable situation, if time is really time and Z_t is really attached to time t . We come back to this in Section 8.6.

A mathematically equivalent definition of causality is that the function $\psi(z)$ is analytic in a neighbourhood of the unit disc $\{z \in \mathbb{C}: |z| \leq 1\}$. This follows, because the Laurent series $\sum_{j=-\infty}^{\infty} \psi_j z^j$ is analytic inside the unit disc if and only if the negative powers of z do not occur. Still another description of causality is that all roots of ϕ are outside the unit circle, because only then is the function $\psi = \theta/\phi$ analytic on the unit disc.

The proof of Theorem 8.8 does not use that Z_t is a white noise process, but only that the series Z_t is bounded in L_1 . Therefore, the same arguments can be used to invert the ARMA-equation in the other direction. If θ has no roots on the unit circle and X_t is stationary, then $\phi(B)X_t = \theta(B)Z_t$ implies that

$$Z_t = \pi(B)X_t = \sum_j \pi_j X_{t-j}, \quad \pi = \frac{\phi}{\theta}.$$

8.14 Definition. An ARMA-process X_t is called *invertible* if, in the preceding representation, the filter is causal: i.e. $\pi_j = 0$ for every $j < 0$.

Equivalent mathematical definitions are that $\pi(z)$ is an analytic function on the unit disc or that θ has all its roots outside the unit circle. In the definition of invertibility we implicitly assume that θ has no roots on the unit circle. The general situation is more technical and is discussed in the next section.

* 8.3 Invertibility

In this section we discuss the proper definition of invertibility in the case that θ has roots on the unit circle. The intended meaning of “invertibility” is that every Z_t can be written as a linear function of the X_s that are prior or simultaneous to t (i.e. $s \leq t$). Two reasonable ways to make this precise are:

- (i) $Z_t = \sum_{j=0}^{\infty} \pi_j X_{t-j}$ for a sequence π_j such that $\sum_{j=0}^{\infty} |\pi_j| < \infty$.
- (ii) Z_t is contained in the closed linear span of $X_t, X_{t-1}, X_{t-2}, \dots$ in $L_2(\Omega, \mathcal{U}, P)$.

In both cases we require that Z_t depends linearly on the prior X_s , but the second requirement is weaker. It turns out that if X_t is a stationary ARMA process relative to Z_t and (i) holds, then the polynomial θ cannot have roots on the unit circle. In that case the definition of invertibility given in the preceding section is appropriate (and equivalent to (i)). However, the requirement (ii) does not exclude the possibility that θ has zeros on the unit circle. An ARMA process is invertible in the sense of (ii) as soon as θ does not have roots *inside* the unit circle.

8.15 Lemma. Let X_t be a stationary ARMA process satisfying $\phi(B)X_t = \theta(B)Z_t$ for polynomials ϕ and θ that are relatively prime.

- (i) Then $Z_t = \sum_{j=0}^{\infty} \pi_j X_{t-j}$ for a sequence π_j such that $\sum_{j=0}^{\infty} |\pi_j| < \infty$ if and only if θ has no roots on or inside the unit circle.
- (ii) If θ has no roots inside the unit circle, then Z_t is contained in the closed linear span of $X_t, X_{t-1}, X_{t-2}, \dots$

Proof. (i). If θ has no roots on or inside the unit circle, then the ARMA process is invertible by the arguments given previously. We must argue the other direction. If Z_t has the given representation, then consideration of the spectral measures gives

$$\frac{\sigma^2}{2\pi} d\lambda = dF_Z(\lambda) = |\pi(e^{-i\lambda})|^2 dF_X(\lambda) = |\pi(e^{-i\lambda})|^2 \frac{|\theta(e^{-i\lambda})|^2}{|\phi(e^{-i\lambda})|^2} \frac{\sigma^2}{2\pi} d\lambda.$$

Hence $|\pi(e^{-i\lambda})\theta(e^{-i\lambda})| = |\phi(e^{-i\lambda})|$ Lebesgue almost everywhere. If $\sum_j |\pi_j| < \infty$, then the function $\lambda \mapsto \pi(e^{-i\lambda})$ is continuous, as are the functions ϕ and θ , and hence this equality must hold for every λ . Since $\phi(z)$ has no roots on the unit circle, nor can $\theta(z)$.

(ii). Suppose that ζ^{-1} is a zero of θ , so that $|\zeta| \leq 1$ and $\theta(z) = (1 - \zeta z)\theta_1(z)$ for a polynomial θ_1 of degree $q - 1$. Define $Y_t = \phi(B)X_t$ and $V_t = \theta_1(B)Z_t$, whence $Y_t = V_t - \zeta V_{t-1}$. It follows that

$$\sum_{j=0}^{k-1} \zeta^j Y_{t-j} = \sum_{j=0}^{k-1} \zeta^j (V_{t-j} - \zeta V_{t-j-1}) = V_t - \zeta^k V_{t-k}.$$

If $|\zeta| < 1$, then the right side converges to V_t in quadratic mean as $k \rightarrow \infty$ and hence it follows that V_t is contained in the closed linear span of Y_t, Y_{t-1}, \dots , which is clearly contained in the closed linear span of X_t, X_{t-1}, \dots , because $Y_t = \phi(B)X_t$. If $q = 1$, then V_t and Z_t are equal up to a constant and the proof is complete. If $q > 1$, then we repeat the argument with θ_1 instead of θ and V_t in the place of Y_t and we shall be finished after finitely many recursions.

If $|\zeta| = 1$, then the right side of the preceding display still converges to V_t as $k \rightarrow \infty$, but only in the weak sense that $E(V_t - \zeta^k V_{t-k})W \rightarrow EV_t W$ for every square integrable variable W . This implies that V_t is in the weak closure of $\text{lin}(Y_t, Y_{t-1}, \dots)$, but this is equal to the strong closure by an application of the Hahn-Banach theorem. Thus we arrive at the same conclusion.

To see the weak convergence, note first that the projection of W onto the closed linear span of $(Z_t: t \in \mathbb{Z})$ is given by $\sum_j \psi_j Z_j$ for some sequence ψ_j with $\sum_j |\psi_j|^2 < \infty$. Because $V_{t-k} \in \text{lin}(Z_s: s \leq t - k)$, we have $|EV_{t-k}W| = |\sum_j \psi_j EV_{t-k}Z_j| \leq \sum_{j \leq t-k} |\psi_j| \text{sd } V_0 \text{sd } Z_0 \rightarrow 0$ as $k \rightarrow \infty$. ■

8.16 Example. The moving average $X_t = Z_t - Z_{t-1}$ is invertible in the sense of (ii), but not in the sense of (i). The moving average $X_t = Z_t - 1.01Z_{t-1}$ is not invertible.

Thus $X_t = Z_t - Z_{t-1}$ implies that $Z_t \in \overline{\text{lin}}(X_t, X_{t-1}, \dots)$. An unexpected phenomenon is that it is also true that Z_t is contained in $\overline{\text{lin}}(X_{t+1}, X_{t+2}, \dots)$. This follows by time reversal: define $U_t = X_{-t+1}$ and $W_t = -Z_{-t}$ and apply the preceding to the

processes $U_t = W_t - W_{t-1}$. Thus it appears that the “opposite” of invertibility is true as well! \square

8.17 EXERCISE. Suppose that $X_t = \theta(B)Z_t$ for a polynomial θ of degree q that has all its roots on the unit circle. Show that $Z_t \in \overline{\text{lin}}(X_{t+q}, X_{t+q+1}, \dots)$. [As in (ii) of the preceding proof, it follows that $V_t = \zeta^{-k}(V_{t+k} - \sum_{j=0}^{k-1} \zeta^j X_{t+k+j})$. Here the first term on the right side converges weakly to zero as $k \rightarrow \infty$.]

8.4 Prediction

As to be expected from their definitions, causality and invertibility are important for calculating predictions for ARMA processes. For a causal and invertible stationary ARMA process X_t satisfying $\phi(B)X_t = \theta(B)Z_t$, we have

$$\begin{aligned} X_t &\in \overline{\text{lin}}(Z_t, Z_{t-1}, \dots), & (\text{by causality}), \\ Z_t &\in \overline{\text{lin}}(X_t, X_{t-1}, \dots), & (\text{by invertibility}). \end{aligned}$$

Here $\overline{\text{lin}}$, the *closed linear span*, is the operation of first forming all (finite) linear combinations and next taking the metric closure in $L_2(\Omega, \mathcal{U}, P)$ of this linear span. The display shows that the two closed linear spans in its right side are identical. Since Z_t is a white noise process, the variable Z_{t+1} is orthogonal to the linear span of Z_t, Z_{t-1}, \dots . By the continuity of the inner product it is then also orthogonal to the closed linear span of Z_t, Z_{t-1}, \dots and hence, under causality, it is orthogonal to X_s for every $s \leq t$. This shows that the variable Z_{t+1} is totally (linearly) unpredictable at time t given the observations X_1, \dots, X_t . This is often interpreted in the sense that in the causal, invertible situation the variable Z_t is an “external noise variable” that is generated at time t “independently” of the history of the system before time t .

Warning. For a general white noise process Z_t the argument delivers orthogonality only, not “independence”.

8.18 EXERCISE. The preceding argument gives that Z_{t+1} is uncorrelated with the system variables X_t, X_{t-1}, \dots of the past. Show that if the variables Z_t are independent, then Z_{t+1} is independent of the system up to time t , not just uncorrelated.

This general discussion readily gives the structure of the best linear predictor for stationary, causal, auto-regressive processes. Suppose that

$$X_{t+1} = \phi_1 X_t + \dots + \phi_p X_{t+1-p} + Z_{t+1}.$$

If $t \geq p$, then X_t, \dots, X_{t-p+1} are perfectly predictable based on the past variables X_1, \dots, X_t : by themselves. If the series is causal, then Z_{t+1} is totally unpredictable (its best prediction is zero), in view of the preceding discussion. Since a best linear predictor

is a projection and projections are linear maps, the best linear predictor of X_{t+1} based on X_1, \dots, X_t is given by

$$\Pi_t X_{t+1} = \phi_t X_1 + \dots + \phi_p X_{t+1-p}, \quad (t \geq p).$$

We should be able to obtain this result also from the prediction equations (2.4) and the explicit form of the auto-covariance function, but that calculation would be more complicated.

8.19 EXERCISE. Find a formula for the best linear predictor of X_{t+2} based on X_1, \dots, X_t , if $t - p \geq 1$.

For moving average and general ARMA processes the situation is more complicated. A similar argument works only for computing the best linear predictor $\Pi_{-\infty, t} X_{t+1}$ based on the infinite past X_t, X_{t-1}, \dots down to time $-\infty$. Assume that X_t is a causal and invertible stationary ARMA process satisfying

$$X_{t+1} = \phi_1 X_t + \dots + \phi_p X_{t+1-p} + Z_{t+1} + \theta_1 Z_t + \dots + \theta_q Z_{t+1-q}.$$

By causality the variable Z_{t+1} is completely unpredictable. By invertibility the variable Z_s is perfectly predictable based on X_s, X_{s-1}, \dots and hence is perfectly predictable based on X_t, X_{t-1}, \dots for every $s \leq t$. Therefore,

$$(8.1) \quad \Pi_{-\infty, t} X_{t+1} = \phi_1 X_t + \dots + \phi_p X_{t+1-p} + \theta_1 Z_t + \dots + \theta_q Z_{t+1-q}.$$

The practical importance of this formula is small, because we never observe the complete past. However, if we observe a long series X_1, \dots, X_t , then the “distant past” X_0, X_{-1}, \dots will not give much additional information over the “recent past” X_t, \dots, X_1 , and $\Pi_{-\infty, t} X_{t+1}$ and the best linear predictor $\Pi_t X_{t+1}$ based on X_1, \dots, X_t will be close.

8.20 Lemma. For a stationary causal, invertible ARMA process X_t there exists constants C and $c < 1$ such that $E|\Pi_{-\infty, t} X_{t+1} - \Pi_t X_{t+1}|^2 \leq Cc^t$ for every t .

Proof. By invertibility we can express Z_s as $Z_s = \sum_{j=0}^{\infty} \pi_j X_{s-j}$, for (π_j) the coefficients of the Taylor expansion of $\pi = \phi/\theta$ around 0. Because this power series has convergence radius bigger than 1, it follows that $\sum_j |\pi_j| R^j < \infty$ for some $R > 1$, and hence $|\pi_j| \leq C_1 c^j$, for some constants $C_1 > 0$, $c < 1$ and every j . By Lemma 1.29 and continuity of a projection $\Pi_t Z_s = \sum_j \pi_j \Pi_t X_{t-s}$. The variables X_{s-j} with $1 \leq s-j \leq t$ are perfectly predictable using X_1, \dots, X_t . We conclude that for $s \leq t$

$$Z_s - \Pi_t Z_s = \sum_{j \geq s} \pi_j (X_{s-j} - \Pi_t X_{s-j}).$$

It follows that $\|Z_s - \Pi_t Z_s\|_2 \leq \sum_{j \geq s} C_1 c^j 2 \|X_1\|_2 \leq C_2 c^s$, for every $s \leq t$.

In view of formula (8.1) for $\Pi_{-\infty, t} X_{t+1}$ and the towering property of projections, the difference between $\Pi_{-\infty, t} X_{t+1}$ and $\Pi_t X_{t+1}$ is equal to $\sum_{j=1}^q \theta_j (Z_{t+1-j} - \Pi_t Z_{t+1-j})$, for $t \geq p$. Thus the L_2 -norm of this difference is bounded above by $\sum_{j=1}^q |\theta_j| \|Z_{t+1-j} - \Pi_t Z_{t+1-j}\|_2$. The lemma follows by inserting the bound obtained in the preceding paragraph. ■

Thus for causal stationary auto-regressive processes the error when predicting X_{t+1} at time $t > p$ using X_t, \dots, X_1 is equal to Z_{t+1} . For general stationary ARMA-processes this is approximately true for large t , and it is exactly true if we include the variables X_0, X_{-1}, \dots in the prediction. It follows that the square *prediction error* $E|X_{t+1} - \Pi_t X_{t+1}|^2$ is equal to the variance $\sigma^2 = EZ_1^2$ of the innovations, exactly in the auto-regressive case, and approximately for general stationary ARMA-processes.

If the innovations are large, the quality of the predictions will be small. Irrespective of the size of the innovations, the possibility of prediction of ARMA-processes into the distant future is limited. The following lemma shows that the predictors converge exponentially fast to the trivial predictor, the constant mean, 0.

8.21 Lemma. *For a stationary causal, invertible ARMA process X_t there exists constants C and $c < 1$ such that $E|\Pi_t X_{t+s}|^2 \leq Cc^s$ for every s and t .*

Proof. By causality, for $s > q$ the variable $\theta(B)Z_{t+s}$ is orthogonal to the variables X_1, \dots, X_t , and hence have best predictor 0. Thus the linearity of prediction and the ARMA equation $X_{t+s} = \phi_1 X_{t+s-1} + \dots + \phi_p X_{t+s-p} + \theta(B)Z_{t+s}$ yield that the variables $Y_s = \Pi_t X_{t+s}$ satisfy $Y_s = \phi_1 Y_{s-1} + \dots + \phi_p Y_{s-p}$, for $s > q$. Writing this equation in vector-form and iterating, we obtain, for $s \geq p$,

$$\begin{pmatrix} Y_s \\ Y_{s-1} \\ \vdots \\ Y_{s-p+1} \end{pmatrix} = \begin{pmatrix} \phi_1 & \phi_2 & \cdots & \phi_{p-1} & \phi_p \\ 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \begin{pmatrix} Y_{s-1} \\ Y_{s-2} \\ \vdots \\ Y_{s-p} \end{pmatrix} = \Phi^{s-p} \begin{pmatrix} Y_p \\ Y_{p-1} \\ \vdots \\ Y_1 \end{pmatrix},$$

where Φ is the matrix in the middle expression. By causality the spectral radius of the matrix Φ is strictly smaller than 1, and this implies that $\|\Phi^s\| \leq Cc^s$ for some constant $c < 1$. (See the proof of Theorem 8.32.) In particular, it follows that $|Y_s|^2 \leq Cc^{2(s-p)} \sum_{i=1}^p Y_i^2$, for $s > p \vee q$. The inequality of the lemma follows by taking expectations. For $s \leq p \vee q$ the inequality is trivially valid for sufficiently large C , because the left side is bounded. ■

8.5 Auto Correlation and Spectrum

The spectral density of an ARMA representation is immediate from the representation $X_t = \psi(B)Z_t$ and Theorem 6.11.

8.22 Theorem. *The stationary ARMA process satisfying $\phi(B)X_t = \theta(B)Z_t$ possesses a spectral density given by*

$$f_X(\lambda) = \left| \frac{\theta(e^{-i\lambda})}{\phi(e^{-i\lambda})} \right|^2 \frac{\sigma^2}{2\pi}.$$

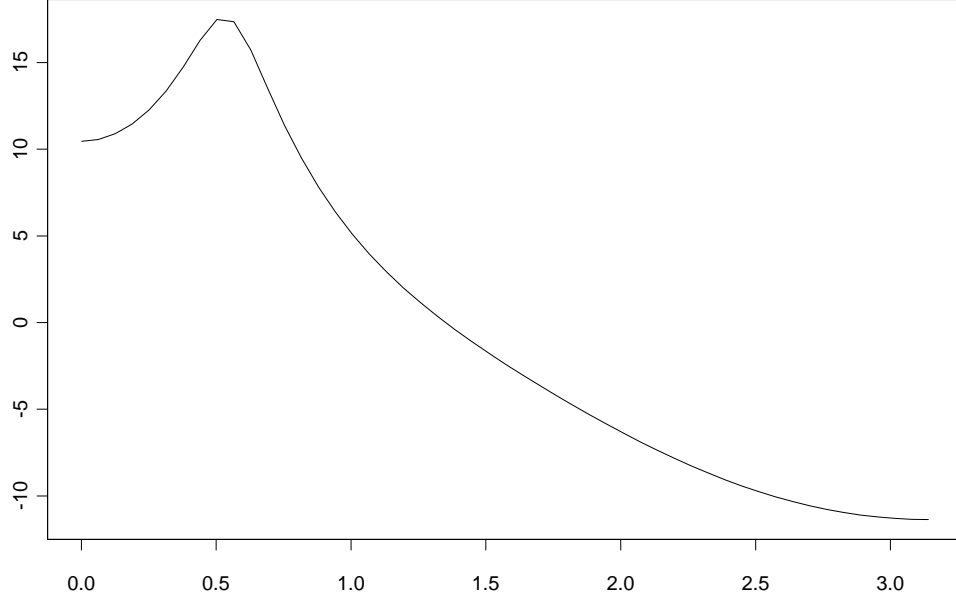

Figure 8.1. Spectral density of the AR series satisfying $X_t - 1.5X_{t-1} + 0.9X_{t-2} - 0.2X_{t-3} + 0.1X_{t-9} = Z_t$. (Vertical axis in *decibels*, i.e. it gives the logarithm of the spectral density.)

8.23 EXERCISE. Plot the spectral densities of the following time series:

- (i) $X_t = Z_t + 0.9Z_{t-1}$;
- (ii) $X_t = Z_t - 0.9Z_{t-1}$;
- (iii) $X_t - 0.7X_{t-1} = Z_t$;
- (iv) $X_t + 0.7X_{t-1} = Z_t$;
- (v) $X_t - 1.5X_{t-1} + 0.9X_{t-2} - 0.2X_{t-3} + 0.1X_{t-9} = Z_t$.

Finding a simple expression for the auto-covariance function is harder, except for the special case of moving average processes, for which the auto-covariances can be expressed in the parameters $\theta_1, \dots, \theta_q$ by a direct computation (cf. Example 1.6 and Lemma 1.29). The auto-covariances of a general stationary ARMA process can be solved from a system of equations. In view of Lemma 1.29(iii), the equation $\phi(B)X_t = \theta(B)Z_t$ leads to the identities, with $\phi(z) = \sum_j \tilde{\phi}_j z^j$ and $\theta(z) = \sum_j \theta_j z^j$,

$$\sum_l \left(\sum_j \tilde{\phi}_j \tilde{\phi}_{j+l-h} \right) \gamma_X(l) = \sigma^2 \sum_j \theta_j \theta_{j+h}, \quad h \in \mathbb{Z}.$$

In principle this system of equations can be solved for the values $\gamma_X(l)$.

An alternative method to compute the auto-covariance function is to write $X_t = \psi(B)Z_t$ for $\psi = \theta/\phi$, whence, by Lemma 1.29(iii),

$$\gamma_X(h) = \sigma^2 \sum_j \psi_j \psi_{j+h}.$$

This requires the computation of the coefficients ψ_j , which can be expressed in the coefficients of ϕ and θ by comparing coefficients in the power series equation $\phi(z)\psi(z) = \theta(z)$. Even in simple situations many ψ_j must be taken into account.

8.24 Example. For the AR(1) series $X_t = \phi X_{t-1} + Z_t$ with $|\phi| < 1$ we obtain $\psi(z) = (1 - \phi z)^{-1} = \sum_{j=0}^{\infty} \phi^j z^j$. Therefore, $\gamma_X(h) = \sigma^2 \sum_{j=0}^{\infty} \phi^j \phi^{j+h} = \sigma^2 \phi^h / (1 - \phi^2)$ for $h \geq 0$. \square

8.25 EXERCISE. Find $\gamma_X(h)$ for the stationary ARMA(1, 1) series $X_t = \phi X_{t-1} + Z_t + \theta Z_{t-1}$ with $|\phi| < 1$.

* **8.26 EXERCISE.** Show that the auto-covariance function of a stationary ARMA process decreases exponentially. Give an estimator of the constant in the exponent in terms of the distance of the zeros of ϕ to the unit circle.

A third method to express the auto-covariance function in the coefficients of the polynomials ϕ and θ uses the spectral representation

$$\gamma_X(h) = \int_{-\pi}^{\pi} e^{ih\lambda} f_X(\lambda) d\lambda = \frac{\sigma^2}{2\pi i} \int_{|z|=1} z^{h-1} \frac{\theta(z)\theta(z^{-1})}{\phi(z)\phi(z^{-1})} dz.$$

The second integral is a contour integral along the positively oriented unit circle in the complex plane. We have assumed that the coefficients of the polynomials ϕ and θ are real, so that $\phi(z)\phi(z^{-1}) = \phi(z)\overline{\phi(z)} = |\phi(z)|^2$ for every z in the unit circle, and similarly for θ . The next step is to evaluate the contour integral with the help of the *residue theorem* from complex function theory.[‡] The poles of the integrand are contained in the set consisting of the zeros v_i and their inverses v_i^{-1} of ϕ and possibly the point 0. The auto-covariance function can be written as a function of the residues at these points.

8.27 Example (ARMA(1, 1)). Consider the stationary ARMA(1, 1) series $X_t = \phi X_{t-1} + Z_t + \theta Z_{t-1}$ with $0 < |\phi| < 1$. The corresponding function $\phi(z)\phi(z^{-1})$ has zeros of multiplicity 1 at the points ϕ^{-1} and ϕ . Both points yield a pole of first order for the integrand in the contour integral. The number ϕ^{-1} is outside the unit circle, so we only need to compute the residue at the second point. The function $\theta(z^{-1})/\phi(z^{-1}) = (z + \theta)/(z - \phi)$ is analytic on the unit disk except at the point ϕ and hence does not contribute other

[‡] Remember that the *residue* at a point z_0 of a meromorphic function f is the coefficient a_{-1} in its Laurent series representation $f(z) = \sum_j a_j (z - z_0)^j$ around z_0 . If f can be written as $h(z)/(z - z_0)^k$ for a function h that is analytic on a neighbourhood of z_0 , then a_{-1} can be computed as $h^{(k-1)}(z_0)/(k-1)!$. For $k = 1$ it is also $\lim_{z \rightarrow z_0} (z - z_0)f(z)$.

poles, but the term z^{h-1} may contribute a pole at 0. For $h \geq 1$ the integrand has poles at ϕ and ϕ^{-1} only and hence

$$\gamma_X(h) = \sigma^2 \operatorname{res}_{z=\phi} z^{h-1} \frac{(1+\theta z)(1+\theta z^{-1})}{(1-\phi z)(1-\phi z^{-1})} = \sigma^2 \phi^h \frac{(1+\theta\phi)(1+\theta/\phi)}{1-\phi^2}.$$

For $h = 0$ the integrand has an additional pole at $z = 0$ and the integral evaluates to the sum of the residues at the two poles at $z = 0$ and $z = \phi$. The first residue is equal to $-\theta/\phi$. Thus

$$\gamma_X(0) = \sigma^2 \left(\frac{(1+\theta\phi)(1+\theta/\phi)}{1-\phi^2} - \frac{\theta}{\phi} \right).$$

The values $\gamma_X(h)$ for $h < 0$ follow by symmetry. \square

8.28 EXERCISE. Find the auto-covariance function for a $\text{MA}(q)$ process by using the residue theorem. (This is not easier than the direct derivation, but perhaps instructive.)

We do not present an additional method to compute the partial auto-correlation function of an ARMA process. However, we make the important observation that for a causal $\text{AR}(p)$ process the partial auto-correlations $\alpha_X(h)$ of lags $h > p$ vanish.

8.29 Theorem. *For a causal $\text{AR}(p)$ process, the partial auto-correlations $\alpha_X(h)$ of lags $h > p$ are zero.*

Proof. This follows by combining Lemma 2.36 and the expression for the best linear predictor found in the preceding section. \blacksquare

8.6 Existence of Causal and Invertible Solutions

In practice we never observe the white noise process Z_t in the definition of an ARMA process. The Z_t are “hidden variables”, whose existence is hypothesized to explain the observed series X_t . From this point of view our earlier question of existence of a stationary solution to the ARMA equation is perhaps not the right question, as it took the sequence Z_t as given. In this section we turn this question around and consider an $\text{ARMA}(p, q)$ process X_t as given. We shall see that there are at least 2^{p+q} white noise processes Z_t such that $\phi(B)X_t = \theta(B)Z_t$ for certain polynomials ϕ and θ of degrees p and q , respectively. (These polynomials depend on the choice of Z_t and hence are not necessarily the ones that are initially given.) Thus the white noise process Z_t is far from being uniquely determined by the observed series X_t . On the other hand, among the multitude of solutions, only one choice yields a representation of X_t as a stationary ARMA process that is both causal and invertible.

8.30 Theorem. *For every stationary ARMA process X_t satisfying $\phi(B)X_t = \theta(B)Z_t$ for polynomials ϕ and θ such that θ has no roots on the unit circle, there exist polynomials ϕ^* and θ^* of the same or smaller degrees as ϕ and θ that have all roots outside the unit disc and a white noise process Z_t^* such that $\phi^*(B)X_t = \theta^*(B)Z_t^*$, almost surely, for every $t \in \mathbb{Z}$.*

Proof. The existence of the stationary ARMA process X_t and our implicit assumption that ϕ and θ are relatively prime imply that ϕ has no roots on the unit circle. Thus all roots of ϕ and θ are either inside or outside the unit circle. We shall move the roots inside the unit circle to roots outside the unit circle by a filtering procedure. Suppose that

$$\phi(z) = -\phi_p(z - v_1) \cdots (z - v_p), \quad \theta(z) = \theta_q(z - w_1) \cdots (z - w_q).$$

Consider any zero z_i of ϕ or θ . If $|z_i| < 1$, then we replace the term $(z - z_i)$ in the above products by the term $(1 - \bar{z}_i z)$; otherwise we keep $(z - z_i)$. For $z_i = 0$, this means that we drop the term $z - z_i = z$ and the degree of the polynomial decreases; otherwise, the degree remains the same. We apply this procedure to all zeros v_i and w_i and denote the resulting polynomials by ϕ^* and θ^* . Because $0 < |z_i| < 1$ implies that $|\bar{z}_i^{-1}| > 1$, the polynomials ϕ^* and θ^* have all zeros outside the unit circle. For z in a neighbourhood of the unit circle,

$$\frac{\theta(z)}{\phi(z)} = \frac{\theta^*(z)}{\phi^*(z)} \kappa(z), \quad \kappa(z) = \prod_{i: |v_i| < 1} \frac{1 - \bar{v}_i z}{z - v_i} \prod_{i: |w_i| < 1} \frac{z - w_i}{1 - \bar{w}_i z}.$$

Because $X_t = (\theta/\phi)(B)Z_t$ and we want that $X_t = (\theta^*/\phi^*)(B)Z_t^*$, we define the process Z_t^* by $Z_t^* = \kappa(B)Z_t$. This is to be understood in the sense that we expand $\kappa(z)$ in its Laurent series $\kappa(z) = \sum_j \kappa_j z^j$ and apply the corresponding linear filter to Z_t .

By construction we now have that $\phi^*(B)X_t = \theta^*(B)Z_t^*$. If $|z| = 1$, then $|1 - \bar{z}_i z| = |z - z_i|$. In view of the definition of κ this implies that $|\kappa(z)| = 1$ for every z on the unit circle and hence Z_t^* has spectral density

$$f_{Z^*}(\lambda) = |\kappa(e^{-i\lambda})|^2 f_Z(\lambda) = 1 \cdot \frac{\sigma^2}{2\pi}.$$

This shows that Z_t^* is a white noise process, as desired. ■

As are many results in time series analysis, the preceding theorem is a result on second moments only. For instance, if Z_t is an i.i.d. sequence, then the theorem does not guarantee that Z_t^* is an i.i.d. sequence as well. Only first and second moments are preserved by the filtering procedure in the proof, in general. Nevertheless, the theorem is often interpreted as implying that not much is lost by assuming a-priori that ϕ and θ have all their roots outside the unit circle.

8.31 EXERCISE. Suppose that the time series Z_t is Gaussian. Show that the series Z_t^* constructed in the preceding proof is Gaussian and hence i.i.d..

8.7 Stability

Let ϕ and θ be polynomials of degrees $p \geq 1$ and $q \geq 0$, with ϕ having no roots on the unit circle. Given initial values X_1, \dots, X_p and a process Z_t , we can recursively define a solution to the ARMA equation $\phi(B)X_t = \theta(B)Z_t$ by

$$(8.2) \quad \begin{aligned} X_t &= \phi_1 X_{t-1} + \dots + \phi_p X_{t-p} + \theta(B)Z_t, & t > p, \\ X_{t-p} &= \phi_p^{-1}(X_t - \phi_1 X_{t-1} - \dots - \phi_{p-1} X_{t-p+1} - \theta(B)Z_t), & t - p < 1. \end{aligned}$$

Theorem 8.8 shows that the only solution X_t that is bounded in L_1 is the (unique) stationary solution $X_t = \psi(B)Z_t$, for $\psi = \theta/\phi$. Hence the solution (8.2) can only be bounded if the initial values X_1, \dots, X_p are chosen randomly according to the stationary distribution. In particular, the process X_t obtained from deterministic initial values must necessarily be unbounded. The “unboundedness” refers to the process $(X_t: t \in \mathbb{Z})$ on the full time scale \mathbb{Z} .

In this section we show that in the causal situation, when ϕ has no zeros on the unit disc, the process X_t tends to stationarity as $t \rightarrow \infty$, given arbitrary initial values. Hence in this case the unboundedness occurs as $t \rightarrow -\infty$. This is another reason to prefer the case that ϕ has no roots on the unit disc: in this case the effect of initializing the process wears off as time goes by.

Let Z_t be a given white noise process and let (X_1, \dots, X_p) and $(\tilde{X}_1, \dots, \tilde{X}_p)$ be two possible sets of initial values, consisting of random variables defined on the same probability space.

8.32 Theorem. *Let ϕ and θ be polynomials such that ϕ has no roots on the unit disc. Let X_t and \tilde{X}_t be the ARMA processes as in defined (8.2) for a given white noise series Z_t and initial values (X_1, \dots, X_p) and $(\tilde{X}_1, \dots, \tilde{X}_p)$, respectively. Then $X_t - \tilde{X}_t \rightarrow 0$ almost surely as $t \rightarrow \infty$.*

8.33 Corollary. *Let ϕ and θ be polynomials such that ϕ has no roots on the unit disc. If for a given white noise series X_t is an ARMA process with arbitrary initial values, then the vector (X_t, \dots, X_{t+k}) converges in distribution to the distribution of the stationary solution to the ARMA equation, as $t \rightarrow \infty$, for every fixed k .*

Proofs. For the corollary we take $(\tilde{X}_1, \dots, \tilde{X}_p)$ equal to the values of the stationary solution. Then we can conclude that the difference between X_t and the stationary solution converges to zero almost surely and hence also in distribution.

For the proof of the theorem we write the ARMA relationship in the “state space form”, for $t > p$,

$$\begin{pmatrix} X_t \\ X_{t-1} \\ \vdots \\ X_{t-p+1} \end{pmatrix} = \begin{pmatrix} \phi_1 & \phi_2 & \cdots & \phi_{p-1} & \phi_p \\ 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \begin{pmatrix} X_{t-1} \\ X_{t-2} \\ \vdots \\ X_{t-p} \end{pmatrix} + \begin{pmatrix} \theta(B)Z_t \\ 0 \\ \vdots \\ 0 \end{pmatrix}.$$

Denote this system by $Y_t = \Phi Y_{t-1} + B_t$. By some algebra it can be shown that

$$\det(\Phi - zI) = (-1)^p z^p \phi(z^{-1}), \quad z \neq 0.$$

Thus the assumption that ϕ has no roots on the unit disc implies that the eigenvalues of Φ are all inside the unit circle. In other words, the spectral radius of Φ , the maximum of the moduli of the eigenvalues, is strictly less than 1. Because the sequence $\|\Phi^n\|^{1/n}$ converges to the spectral radius as $n \rightarrow \infty$, we can conclude that $\|\Phi^n\|^{1/n}$ is strictly less than 1 for all sufficiently large n , and hence $\|\Phi^n\| \rightarrow 0$ as $n \rightarrow \infty$. (In fact, if $\|\Phi^{n_0}\| = c < 1$, then $\|\Phi^{kn_0}\| \leq c^k$ for every natural number k and hence $\|\Phi^n\| \leq Cc^{\lfloor n/n_0 \rfloor}$ for every n , for $C = \max_{0 \leq j \leq n_0} \|\Phi^j\|$, and the convergence to zero is exponentially fast.)

If \tilde{Y}_t relates to \tilde{X}_t as Y_t relates to X_t , then $Y_t - \tilde{Y}_t = \Phi^{t-p}(Y_p - \tilde{Y}_p) \rightarrow 0$ almost surely as $t \rightarrow \infty$. ■

8.34 EXERCISE. Suppose that $\phi(z)$ has no zeros on the unit circle and at least one zero inside the unit circle. Show that there exist initial values (X_1, \dots, X_p) such that the resulting process X_t is not bounded in probability as $t \rightarrow \infty$. [Let \tilde{X}_t be the stationary solution and let X_t be the solution given initial values (X_1, \dots, X_p) . Then, with notation as in the preceding proof, $Y_t - \tilde{Y}_t = \Phi^{t-p}(Y_p - \tilde{Y}_p)$. Choose an appropriate deterministic vector for $Y_p - \tilde{Y}_p$.]

8.35 EXERCISE. Simulate a series of length 200 of the ARMA process satisfying $X_t - 1.3X_{t-1} + 0.7X_{t-2} = Z_t + 0.7Z_{t-1}$. Plot the sample path, and the sample auto-correlation and sample partial auto-correlation functions. Vary the distribution of the innovations and simulate both stationary and nonstationary versions of the process.

8.8 ARIMA Processes

In Chapter 1 differencing was introduced as a method to transform a nonstationary time series into a stationary one. This method is particularly attractive in combination with ARMA modelling: in the notation of the present chapter the differencing filters can be written as

$$\nabla X_t = (1 - B)X_t, \quad \nabla^d X_t = (1 - B)^d X_t, \quad \nabla_k X_t = (1 - B^k)X_t.$$

Thus the differencing filters ∇ , ∇^d and ∇_k correspond to applying the operator $\eta(B)$ for the polynomials $\eta(z) = 1 - z$, $\eta(z) = (1 - z)^d$ and $\eta(z) = (1 - z^k)$, respectively. These polynomials have in common that all their roots are on the complex unit circle. Thus they were “forbidden” polynomials in our preceding discussion of ARMA processes.

By Theorem 8.10, for the three given polynomials η the series $Y_t = \eta(B)X_t$ cannot be a stationary ARMA process relative to polynomials without zeros on the unit circle if X_t is a stationary process. Indeed, if also $\phi(B)Y_t = \theta(B)Z_t$, then $(\phi\eta)(B)X_t = \theta(B)Z_t$, and stationarity of X_t would imply that $\phi\eta$ has no roots on the unit circle. On the other hand, the series $Y_t = \eta(B)X_t$ can well be a stationary ARMA process if X_t is a non-stationary time series. Thus we can use polynomials with roots on the unit circle to extend the domain of ARMA modelling to nonstationary time series.

8.36 Definition. A time series X_t is an $ARIMA(p, d, q)$ process if $\nabla^d X_t$ is a stationary $ARMA(p, q)$ process.

In other words, the time series X_t is an $ARIMA(p, d, q)$ process if there exist polynomials ϕ and θ of degrees p and q and a white noise series Z_t such that the time series $\nabla^d X_t$ is stationary and $\phi(B)\nabla^d X_t = \theta(B)Z_t$ almost surely. The additional “I” in ARIMA is for “integrated”. If we view taking differences ∇^d as differentiating, then the definition requires that the d th derivative of X_t is a stationary ARMA process, whence X_t itself is an “integrated ARMA process”.

The following definition goes a step further.

8.37 Definition. A time series X_t is a $SARIMA(p, d, q)(P, D, Q, per)$ process if there exist polynomials ϕ , θ , Φ and Θ of degrees p , q , P and Q and a white noise series Z_t such that the time series $\nabla_{per}^D \nabla^d X_t$ is stationary and $\Phi(B^{per})\phi(B)\nabla_{per}^D \nabla^d X_t = \Theta(B^{per})\theta(B)Z_t$ almost surely.

The “S” in SARIMA is short for “seasonal”. The idea of a seasonal model is that we might only want to use certain powers B^{per} of the backshift operator in our model, because the series is thought to have a certain period. Including the terms $\Phi(B^{per})$ and $\Theta(B^{per})$ does not make the model more general (as these terms could be subsumed in $\phi(B)$ and $\theta(B)$), but reflects our a-priori idea that certain coefficients in the polynomials are zero. This a-priori knowledge will be important when estimating the coefficients from an observed time series.

Modelling an observed time series by an ARIMA, or SARIMA, model has become popular through an influential book by Box and Jenkins. A given time series X_t may be differenced, repeatedly if necessary, until it is perceived as being stationary, and next the differenced series modelled as a stationary ARMA process. This unified filtering paradigm of a *Box-Jenkins analysis* is indeed attractive. The popularity is probably also due to the compelling manner in which Box and Jenkins explain the reader how he or she must set up the analysis, going through a fixed number of steps. They thus provide the data-analyst with a clear algorithm to carry out an analysis that is intrinsically difficult. It is obvious that the results of such an analysis will not always be good, but an alternative is less obvious.

* 8.9 VARMA Processes

A *VARMA process* is a vector-valued ARMA process. Given matrices Φ_j and Θ_j and a white noise sequence Z_t of dimension d , a VARMA(p, q) process satisfies the relationship

$$X_t = \Phi_1 X_{t-1} + \Phi_2 X_{t-2} + \cdots + \Phi_p X_{t-p} + Z_t + \Theta_1 Z_{t-1} + \cdots + \Theta_q Z_{t-q}.$$

The theory for VARMA process closely resembles the theory for ARMA processes. The role of the polynomials ϕ and θ is taken over by the matrix-valued polynomials

$$\begin{aligned}\Phi(z) &= 1 - \Phi_1 z - \Phi_2 z^2 - \cdots - \Phi_p z^p, \\ \Theta(z) &= 1 + \Theta_1 z + \Theta_2 z^2 + \cdots + \Theta_q z^q.\end{aligned}$$

These identities and sums are to be interpreted entry-wise and hence Φ and Θ are $(d \times d)$ -matrices with entries that are polynomials in $z \in \mathbb{C}$.

Instead of looking at zeros of polynomials we must now look at the values of z for which the matrices $\Phi(z)$ and $\Theta(z)$ are singular. Equivalently, we must look at the zeros of the complex functions $z \mapsto \det \Phi(z)$ and $z \mapsto \det \Theta(z)$. Apart from this difference, the conditions for existence of a stationary solution, causality and invertibility are the same.

8.38 Theorem. *If the matrix-valued polynomial $\Phi(z)$ is invertible for every z in the unit circle, then there exists a unique stationary solution X_t to the VARMA equations. If the matrix-valued polynomial $\Phi(z)$ is invertible for every z on the unit disc, then this can be written in the form $X_t = \sum_{j=0}^{\infty} \Psi_j Z_{t-j}$ for matrices Ψ_j with $\sum_{j=0}^{\infty} \|\Psi_j\| < \infty$. If, moreover, the polynomial $\Theta(z)$ is invertible for every z on the unit disc, then we also have that $Z_t = \sum_{j=0}^{\infty} \Pi_j X_{t-j}$ for matrices Π_j with $\sum_{j=0}^{\infty} \|\Pi_j\| < \infty$.*

The norm $\|\cdot\|$ in the preceding may be any matrix norm. The proof of this theorem is the same as the proofs of the corresponding results in the one-dimensional case, in view of the following observations.

A series of the type $\sum_{j=-\infty}^{\infty} \Psi_j Z_{t-j}$ for matrices Ψ_j with $\sum_{j=0}^{\infty} \|\Psi_j\| < \infty$ and a vector-valued process Z_t with $\sup_t E\|Z_t\| < \infty$ converges almost surely and in mean. We can define a vector-valued function Ψ with domain at least the complex unit circle by $\Psi(z) = \sum_{j=-\infty}^{\infty} \Psi_j z^j$, and write the series as $\Psi(B)Z_t$, as usual.

Next, the analogue of Lemma 8.2 is true. The product $\Psi = \Psi_1 \Psi_2$ of two matrix-valued functions $z \mapsto \Psi_i(z)$ is understood to be the function $z \mapsto \Psi(z)$ with $\Psi(z)$ equal to the matrix-product $\Psi_1(z)\Psi_2(z)$.

8.39 Lemma. *If $(\Psi_{j,1})$ and $(\Psi_{j,2})$ are sequences of $(d \times d)$ -matrices with $\sum_j \|\Psi_{j,i}\| < \infty$ for $i = 1, 2$, then the function $\Psi = \Psi_1 \Psi_2$ can be expanded as $\Psi(z) = \sum_{j=-\infty}^{\infty} \Psi_j z^j$, at least for $z \in S^1$, for matrices Ψ_j with $\sum_{j=-\infty}^{\infty} \|\Psi_j\| < \infty$. Furthermore $\Psi(B)X_t = \Psi_1(B)[\Psi_2(B)X_t]$, almost surely, for every time series X_t with $\sup_t E\|X_t\| < \infty$.*

The functions $z \mapsto \det \Phi(z)$ and $z \mapsto \det \Theta(z)$ are polynomials. Hence if they are nonzero on the unit circle, then they are nonzero on an open annulus containing the unit circle, and the matrices $\Phi(z)$ and $\Theta(z)$ are invertible for every z in this annulus. Cramer's

rule, which expresses the solution of a system of linear equations in determinants, shows that the entries of the inverse matrices $\Phi(z)^{-1}$ and $\Theta(z)^{-1}$ are quotients of polynomials. The denominators are the determinants $\det \Phi(z)$ and $\det \Theta(z)$ and hence are nonzero in a neighbourhood of the unit circle. These matrices may thus be expanded (entrywise) in Laurent series

$$\Phi(z)^{-1} = \left(\sum_{j=-\infty}^{\infty} (\Phi_j)_{k,l} z^j \right)_{k,l=1,\dots,d} = \sum_{j=-\infty}^{\infty} \Phi_j z^j,$$

where the Φ_j are matrices such that $\sum_{j=-\infty}^{\infty} \|\Phi_j\| < \infty$, and similarly for $\Theta(z)^{-1}$. This allows the back-shift calculus that underlies the proof of Theorem 8.8. For instance, the matrix-valued function $\Psi = \Phi^{-1}\Theta$ is well-defined on the unit circle, and can be expanded as $\Psi(z) = \sum_{j=-\infty}^{\infty} \Psi_j z^j$ for matrices Ψ_j with $\sum_{j=-\infty}^{\infty} \|\Psi_j\| < \infty$. The process $\Psi(B)Z_t$ is the unique solution to the VARMA-equation.

* 8.10 ARMA-X Processes

The (V)ARMA-relation models a time series as an autonomous process, whose evolution is partially explained by its own past (or the past of the other coordinates in the vector-valued situation). It is often of interest to include additional explanatory variables into the model. The natural choice of including time-dependent, vector-valued variables W_t linearly yields the *ARMA-X* model

$$X_t = \Phi_1 X_{t-1} + \Phi_2 X_{t-2} + \dots + \Phi_p X_{t-p} + Z_t + \Theta_1 Z_{t-1} + \dots + \Theta_q Z_{t-q} + \beta^T W_t.$$

9

GARCH Processes

White noise processes are basic building blocks for time series models, but can also be of interest on their own. In particular, GARCH processes are white noises that have been found useful for modelling financial time series. Until some decades ago the “random walk hypothesis”, according to which financial returns are independent random variables, was the accepted model in finance. The famous Black-Scholes model that underlies option-pricing theory falls into this category. Then in the 1980s it was realized that although returns appear to have zero autocorrelation, they are not independent. In 2003 Engle and Granger received a Nobel prize for pointing this out and introducing models from white noise series that are not i.i.d.

Figure 9.1 shows a realization of a GARCH process. The striking feature are the “bursts of activity”, which alternate with “quiet” periods of the series. The frequency of the movements of the series appears to be constant over time, but their amplitude changes, alternating between “volatile” periods (large amplitude) and quiet periods. This phenomenon is referred to as *volatility clustering*. A look at the auto-correlation function of the realization, Figure 9.2, shows that the alternations are not reflected in the second moments of the series: the series can be modelled as white noise.

Recall that a *white noise* series is any mean-zero stationary time series whose auto-covariances at nonzero lags vanish. We shall speak of a *heteroscedastic white noise* if the auto-covariances at nonzero lags vanish, but the variances are possibly time-dependent. A related concept is that of a martingale difference series. Recall that a *filtration* \mathcal{F}_t is a nondecreasing collection of σ -fields $\cdots \subset \mathcal{F}_{-1} \subset \mathcal{F}_0 \subset \mathcal{F}_1 \subset \cdots$. A *martingale difference series* relative to the filtration \mathcal{F}_t is a time series X_t such that X_t is \mathcal{F}_t -measurable and $E(X_t | \mathcal{F}_{t-1}) = 0$, almost surely, for every t . (The latter implicitly includes the assumption that $E|X_t| < \infty$, so that the conditional expectation is well defined.)

Any martingale difference series X_t with finite second moments is a (possibly heteroscedastic) white noise series. Indeed, the equality $E(X_t | \mathcal{F}_{t-1}) = 0$ is equivalent to orthogonality of X_t to all random variables $Y \in \mathcal{F}_{t-1}$, which includes the variables $X_s \in \mathcal{F}_s \subset \mathcal{F}_{t-1}$ for every $s < t$; consequently $EX_t X_s = 0$ for every $s < t$. The converse is false: not every white noise is a martingale difference series (relative to a natural filtra-

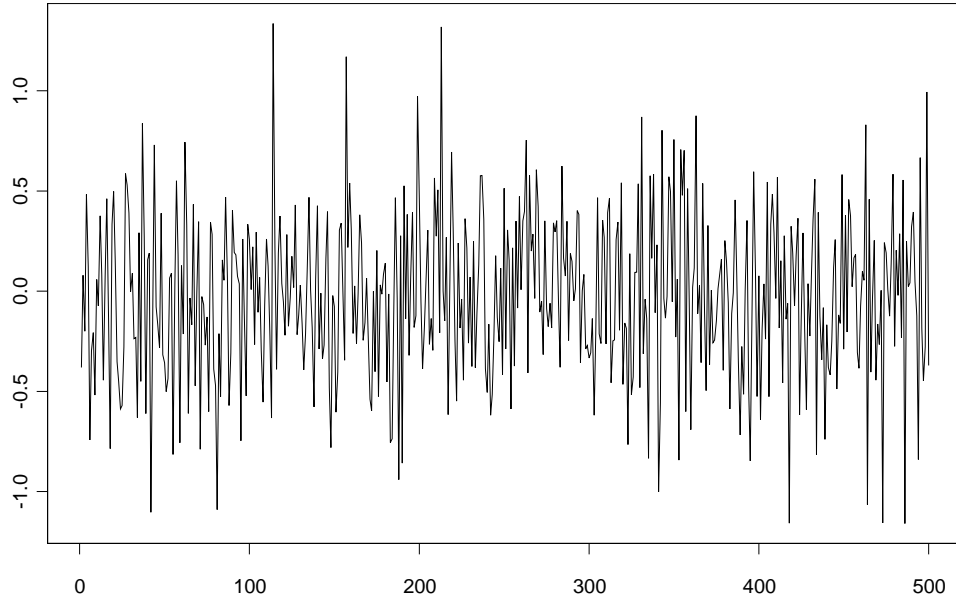

Figure 9.1. Realization of length 500 of the stationary Garch(1, 1) process with $\alpha = 0.15$, $\phi_1 = 0.4$, $\theta_1 = 0.4$ and standard normal variables Z_t .

tion). This is because $E(X|Y) = 0$ implies that X is orthogonal to *all* square-integrable, measurable functions of Y , not just to linear functions.

9.1 EXERCISE. If X_t is a martingale difference series, show that $E(X_{t+k}X_{t+l}|\mathcal{F}_t) = 0$ almost surely for every $k \neq l > 0$. Thus “future variables are uncorrelated given the present”. Find a white noise series which lacks this property relative to its natural filtration.

By definition a martingale difference sequence has zero conditional first moment given the past. A natural step for further modelling is to postulate a specific form of the conditional second moment. This is exactly what GARCH models are about. Thus they are also concerned only with first and second moments of the time series, albeit conditional moments. The attraction of GARCH processes is that they can capture many features of observed time series, in particular those in finance, that ARMA processes cannot. Besides volatility clustering these *stylized facts* include leptokurtic (i.e. heavy) tailed marginal distributions and nonzero auto-correlations for the process X_t^2 of squares. (The phrase “stylized fact” is used for salient properties that seem to be shared by many financial time series, but “fact” is not to be taken literally.)

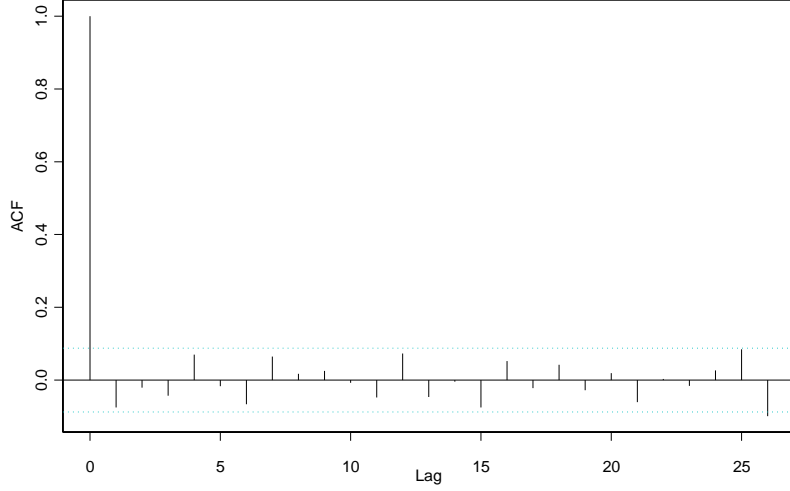

Figure 9.2. Sample auto-covariance function of the time series in Figure 9.1.

There are many types of GARCH processes. We discuss a selection in the following sections, paying most attention to linear GARCH processes.

9.1 Linear GARCH

Linear GARCH processes were the earliest GARCH processes to be studied, and may be viewed as *the* GARCH processes.

9.2 Definition. A GARCH (p, q) process X_t is a martingale difference sequence relative to a given filtration \mathcal{F}_t , whose conditional variances $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$ exist and satisfy, for every $t \in \mathbb{Z}$ and given nonnegative constants $\alpha > 0, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$,

$$(9.1) \quad \sigma_t^2 = \alpha + \phi_1 \sigma_{t-1}^2 + \dots + \phi_p \sigma_{t-p}^2 + \theta_1 X_{t-1}^2 + \dots + \theta_q X_{t-q}^2, \quad \text{a.s.}$$

With the notations $\phi(z) = 1 - \phi_1 z - \dots - \phi_p z^p$ and $\theta(z) = \theta_1 z + \dots + \theta_q z^q$, the equation for the conditional variance $\sigma_t^2 = \text{var}(X_t | \mathcal{F}_{t-1})$ can be abbreviated to

$$\phi(B)\sigma_t^2 = \alpha + \theta(B)X_t^2.$$

This notation is as in Chapter 8 except that the polynomial θ has zero intercept: $\theta_0 = 0$. If the coefficients ϕ_1, \dots, ϕ_p all vanish, then σ_t^2 is modelled as a linear function of $X_{t-1}^2, \dots, X_{t-q}^2$. This is called an ARCH (q) model, from “auto-regressive conditional heteroscedastic”. The additional G of GARCH is for the nondescript “generalized”.

Since $\sigma_t > 0$ (as $\alpha > 0$), we can define auxiliary variables by $Z_t = X_t/\sigma_t$. The martingale difference property of $X_t = \sigma_t Z_t$ and the definition of σ_t^2 as the conditional variance (which shows that $\sigma_t^2 \in \mathcal{F}_{t-1}$) imply

$$(9.2) \quad \mathbb{E}(Z_t | \mathcal{F}_{t-1}) = 0, \quad \mathbb{E}(Z_t^2 | \mathcal{F}_{t-1}) = 1.$$

Thus the time series Z_t is a *scaled martingale difference series*. By reversing this construction we can easily define GARCH processes on the time set \mathbb{Z}^+ . Here we could start for instance with an i.i.d. sequence Z_t of variables with mean zero and variance 1.

9.3 Lemma. *Let $(Z_t: t \in \mathbb{Z})$ be a martingale difference sequence that satisfies (9.2) relative to an arbitrary filtration \mathcal{F}_t and let $\sigma_0, \sigma_{-1}, \dots, \sigma_{-r+1}$ for be random variables with $\sigma_t \in \mathcal{F}_{t-1}$ defined on the same probability space, where $r = p \vee q$. Then the definitions $X_t = \sigma_t Z_t$ for $t = 0, -1, \dots, -r + 1$ followed by the recursions, for $t \geq 1$,*

$$\begin{cases} \sigma_t^2 = \alpha + \phi_1 \sigma_{t-1}^2 + \dots + \phi_p \sigma_{t-p}^2 + \theta_1 X_{t-1}^2 + \dots + \theta_q X_{t-q}^2, \\ X_t = \sigma_t Z_t \end{cases},$$

define a GARCH process $(X_t: t \geq 1)$ with conditional variance process $\sigma_t^2 = \mathbb{E}(X_t^2 | \mathcal{F}_{t-1})$. Furthermore $\sigma_t \in \mathcal{F}_{t-1}$ and $\mathcal{F}_0 \vee \sigma(X_s: 1 \leq s \leq t) = \mathcal{F}_0 \vee \sigma(Z_s: 1 \leq s \leq t)$, for every t .

Proof. The set of four assertions $\sigma_t \in \mathcal{F}_{t-1}$, $X_t \in \mathcal{F}_t$, $\mathbb{E}(X_t | \mathcal{F}_{t-1}) = 0$, $\mathbb{E}(X_t^2 | \mathcal{F}_{t-1}) = \sigma_t^2$ follows for $t \leq 0$ from the assumptions and definitions. In view of the recursive definitions the set of assertions extends to $t \geq 1$ by induction. Thus all requirements for a GARCH process are satisfied for $t \geq 1$.

The recursion formula for σ_t^2 shows that $\sigma_t \in \mathcal{F}_0 \vee \sigma(X_s, Z_s: 1 \leq s \leq t-1)$. The equality $\mathcal{F}_0 \vee \sigma(Z_s: 1 \leq s \leq t) = \mathcal{F}_0 \vee \sigma(X_s: 1 \leq s \leq t)$ is clearly valid for $t = 0$, and next follows by induction for every $t \geq 1$, since $X_t = \sigma_t Z_t$ and $Z_t = X_t/\sigma_t$, where σ_t is a function of σ_s and X_s with $s < t$. This yields the final assertion of the lemma. ■

Time in the definition of GARCH processes flows in one direction (the natural one), by the presence of the filtration \mathcal{F}_t . For this reason the GARCH relation cannot be used backwards to construct the conditional variances σ_t^2 and process X_t at past times, unlike for ARMA processes. As a consequence the lemma constructs the time series X_t only for positive times. The same construction works starting from any time, but, depending on the initialization, it cannot necessarily be extended to the full time set \mathbb{Z} while keeping the GARCH relation and correct time flow.

* **9.4 EXERCISE.** Lemma 9.3 constructs a GARCH (1,1) process for times $t \geq 0$ starting from a filtration \mathcal{F}_t , an MDS Z_t , and an initial value $\sigma_0 \in \mathcal{F}_0$. Show that it extends to the full time scale \mathbb{Z} if and only if, for every $j \geq 0$,

$$\frac{\sigma_0^2 - \alpha - \alpha W_{-1} W_{-2} - \dots - \alpha W_{-1} \cdots W_{-j}}{W_{-1} W_{-2} \cdots W_{-j-1}} \in \mathcal{F}_{-j-1},$$

where $W_t = \phi_1 + \theta_1 Z_t^2$. In particular, if $\theta_1 = 0$ this is equivalent to $\sigma_0 \in \mathcal{F}_t$ for every $t < 0$. If in the latter case we enlarge the filtration to $\mathcal{F}_t \vee \sigma(\sigma_0)$, is Z_t then necessarily still an MDS? [The GARCH relation and $X_t = \sigma_t Z_t$ imply that $\sigma_t^2 = \alpha + W_{t-1} \sigma_{t-1}^2$. Use this in reverse time to express σ_t^2 for $t < 0$ in σ_0 and W_t, \dots, W_1 .]

Lemma 9.3 uses $p \vee q$ initial values $\sigma_0, \dots, \sigma_{-r+1}$. As these can be chosen in many ways, the process is not unique. The construction of *stationary* GARCH processes is more involved and taken up in Section 9.1.2. Next in Section 9.1.3 the effect of initialization is shown to wear off as $t \rightarrow \infty$: any process as constructed in the preceding lemma will tend to the stationary solution, *if* such a solution exists.

The final assertion of the lemma shows that at each time instance the randomness added “into the system” is generated by Z_t . This encourages to interpret this standardized process as the *innovations* of a GARCH process, although this term should now be understood in a multiplicative sense.

As any martingale differences series, a GARCH process is “constant in the mean”. Not only is its mean function zero, but also at each time its expected change given its past is zero. The (conditional) variance structure of a GARCH process is more interesting. By the GARCH relation (9.1) large absolute values X_{t-1}, \dots, X_{t-q} of the process at times $t-1, \dots, t-q$ lead to a large conditional variance σ_t^2 at time t . Then the value $X_t = \sigma_t Z_t$ of the time series at time t tends to deviate from far from zero as well (depending on the size of the innovation Z_t). Large conditional variances $\sigma_{t-1}^2, \dots, \sigma_{t-p}^2$ similarly promote large values of $|X_t|$. In financial applications (conditional) variance is often referred to as *volatility*, and strongly fluctuating time series are said to be *volatile*. Thus GARCH processes tend to alternate periods of high and low volatility. This *volatility clustering* is one of the *stylized facts* of financial time series.

A second *stylized fact* are the leptokurtic tails of the marginal distribution of a typical financial time series. A distribution on \mathbb{R} is called *leptokurtic* if it has fat tails, for instance fatter than normal tails. A quantitative measure of “fatness” of the tails of the distribution of a random variable X is the *kurtosis* defined as $\bar{\kappa}_4(X) = E(X - EX)^4 / (\text{var } X)^2$. If $X_t = \sigma_t Z_t$, where σ_t is \mathcal{F}_{t-1} -measurable and Z_t is independent of \mathcal{F}_{t-1} with mean zero and variance 1, then $EX_t^2 = E\sigma_t^2$, $EX_t^4 = E\sigma_t^4 E Z_t^4 = E\sigma_t^4 \bar{\kappa}_4(Z_t)$ and

$$\frac{\bar{\kappa}_4(X_t)}{\bar{\kappa}_4(Z_t)} = \frac{EX_t^4 / (EX_t^2)^2}{\bar{\kappa}_4(Z_t)} = \frac{E\sigma_t^4}{(E\sigma_t^2)^2} = \frac{\text{var } \sigma_t^2 + (E\sigma_t^2)^2}{(E\sigma_t^2)^2} = 1 + \frac{\text{var } \sigma_t^2}{(E\sigma_t^2)^2}.$$

Thus $\bar{\kappa}_4(X_t) \geq \bar{\kappa}_4(Z_t)$, and the difference can be substantial if the variance of the volatility σ_t^2 is large. It follows that the GARCH structure is also able to capture some of the observed leptokurtosis of financial time series.

As the kurtosis of a normal variable is equal to 3, the kurtosis of a GARCH series X_t driven by Gaussian innovations Z_t is always bigger than 3. It has been observed that this usually does not go far enough in explaining “excess kurtosis” over the normal distribution. The use of a Student t-distribution can improve the fit of a GARCH process substantially.

If we define $W_t = X_t - \sigma_t^2$ and replace σ_t^2 by $X_t^2 - W_t$ in (9.1), then we find after

rearranging the terms,

$$(9.3) \quad \begin{aligned} X_t^2 = & \alpha + (\phi_1 + \theta_1)X_{t-1}^2 + \cdots + (\phi_r + \theta_r)X_{t-r}^2 \\ & + W_t - \phi_1 W_{t-1} - \cdots - \phi_p W_{t-p}, \end{aligned}$$

where $r = p \vee q$ and the sequences ϕ_1, \dots, ϕ_p or $\theta_1, \dots, \theta_q$ are padded with zeros to increase their lengths to r , if necessary. We can abbreviate this to

$$(\phi - \theta)(B)X_t^2 = \alpha + \phi(B)W_t, \quad W_t = X_t^2 - E(X_t^2 | \mathcal{F}_{t-1}).$$

This is the characterizing equation for an ARMA(r, r) process X_t^2 relative to the noise process W_t . The variable $W_t = X_t^2 - \sigma_t^2$ is the prediction error when predicting X_t^2 by its conditional expectation $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$ and hence W_t is orthogonal to \mathcal{F}_{t-1} . Thus W_t is a martingale difference series and hence a white noise sequence if its second moments exist and are independent of t . Under these conditions the time series of squares X_t^2 is an ARMA process in the sense of Definition 8.4. This observation is useful to compute certain characteristics of the process.

Warning. The variables W_t in equation (9.3) are defined in terms of the process X_t (their squares and conditional variances) and therefore do not have an interpretation as an exogenous noise process that drives the process X_t^2 . This circularity makes that one should not apply results on ARMA processes unthinkingly to the process X_t^2 . For instance, equation (9.3) seems to have little use for proving existence of solutions to the GARCH equation, although some authors seem to believe otherwise.

* **9.5 EXERCISE.** Suppose that X_t and W_t are martingale difference series relative to a given filtration such that $\phi(B)X_t^2 = \theta(B)W_t$ for polynomials ϕ and θ of degrees p and q . Show that X_t is a GARCH process. Does strict stationarity of the time series X_t^2 or W_t imply strict stationarity of the time series X_t ?

9.6 EXERCISE. Write σ_t^2 as the solution to an ARMA($p \vee q, q - 1$) equation by substituting $X_t^2 = \sigma_t^2 + W_t$ in (9.3).

9.1.1 Autocovariances of Squares

Even though the autocorrelation function of a GARCH process vanishes (at every nonzero lag), the variables are not independent. One way of seeing this is to consider the autocorrelations of the squares X_t^2 of the time series. Independence of the X_t would imply independence of the X_t^2 , and hence a zero autocorrelation function. However, in view of (9.3) the squares form an ARMA process, whence their autocorrelations are nonzero. The auto-correlations of the squares of financial time series are typically observed to be positive at all lags, another *stylized fact* of such series.

The auto-correlation function of the squares of a GARCH series will exist under appropriate additional conditions on the coefficients and the driving noise process Z_t . The ARMA relation (9.3) for the square process X_t^2 may be used to derive this function from the formulas for ARMA processes. Here we must not forget that the process W_t

in (9.3) is defined through X_t and hence its variance depends on the parameters in the GARCH relation.

Actually, equation (9.3) is an ARMA equation “with intercept α ”. Provided that $\beta := (\phi - \theta)(1) = 1 - \sum_j (\phi_j + \theta_j) \neq 0$, we can rewrite the equation as $(\phi - \theta)(B)(X_t^2 - \alpha/\beta) = \phi(B)W_t$, which shows that the time series X_t^2 is an ARMA process plus α/γ . The autocorrelations are of course independent of this shift.

9.7 Example (GARCH(1,1)). The conditional variances of a GARCH(1,1) process satisfy $\sigma_t^2 = \alpha + \phi\sigma_{t-1}^2 + \theta X_{t-1}^2$. If we assume the process X_t to be stationary, then $E\sigma_t^2 = EX_t^2$ is independent of t . Taking the expectation across the GARCH equation and rearranging then immediately gives

$$E\sigma_t^2 = EX_t^2 = \frac{\alpha}{1 - \phi - \theta}.$$

To compute the auto-correlation function of the time series of squares X_t^2 , we employ (9.3), which reveals this process as an ARMA(1,1) process with the auto-regressive and moving average polynomials given as $1 - (\phi + \theta)z$ and $1 - \phi z$, respectively. The calculations in Example 8.27 yield that

$$\begin{aligned}\gamma_{X^2}(h) &= \tau^2(\phi + \theta)^h \frac{(1 - \phi(\phi + \theta))(1 - \phi/(\phi + \theta))}{1 - (\phi + \theta)^2}, \quad h > 0, \\ \gamma_{X^2}(0) &= \tau^2 \left(\frac{(1 - \phi(\phi + \theta))(1 - \phi/(\phi + \theta))}{1 - (\phi + \theta)^2} + \frac{\phi}{\phi + \theta} \right).\end{aligned}$$

Here τ^2 is the variance of the process $W_t = X_t^2 - E(X_t^2 | \mathcal{F}_{t-1})$, and is also dependent on the parameters θ and ϕ . By squaring the GARCH equation we find

$$\sigma_t^4 = \alpha^2 + \phi^2\sigma_{t-1}^4 + \theta^2 X_{t-1}^4 + 2\alpha\phi\sigma_{t-1}^2 + 2\alpha\theta X_{t-1}^2 + 2\phi\theta\sigma_{t-1}^2 X_{t-1}^2.$$

If Z_t is independent of \mathcal{F}_{t-1} , then $E\sigma_t^2 X_t^2 = E\sigma_t^4$ and $EX_t^4 = \bar{\kappa}_4(Z_t)E\sigma_t^4$. If we assume, moreover, that the moments exist and are independent of t , then we can take the expectation across the preceding display and rearrange to find that

$$E\sigma_t^4(1 - \phi^2 - 2\phi\theta - \kappa_4(Z)\theta^2) = \alpha^2 + (2\alpha\phi + 2\alpha\theta)E\sigma_t^2.$$

Together with the formulas obtained previously, this gives the variance of W_t , since $EW_t = 0$ and $EW_t^2 = EX_t^4 - E\sigma_t^4$, by Pythagoras' identity for projections. \square

9.8 EXERCISE. Find the auto-covariance function of the process σ_t^2 for a GARCH(1,1) process.

9.9 EXERCISE. Find an expression for the kurtosis of the (marginal) distribution of X_t in a stationary GARCH(1,1) process as in the preceding example. Let Z_t be Gaussian. For which parameter values is the formula valid? What happens if the parameters approach the boundary of this set?

9.1.2 Stationary Solutions

Because the GARCH relation is recursive and the variables X_t enter it both explicitly and implicitly (through their conditional variances), existence of *stationary* GARCH processes is far from obvious. In this section we show that a (strictly) stationary solution exists only for certain parameter values $\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$, and if it exists, then it is unique. Surprisingly, there are certain parameter values for which a *strictly* stationary solution exists, but not a (second order) stationary solution.

The key to understanding these results is a state space representation, which ‘repairs’ the circularity of the GARCH definition. By substituting $X_{t-1} = \sigma_{t-1}Z_{t-1}$ in the GARCH equation (9.1), and leaving X_{t-2}, \dots, X_{t-q} untouched, we see that

$$(9.4) \quad \sigma_t^2 = \alpha + (\phi_1 + \theta_1 Z_{t-1}^2)\sigma_{t-1}^2 + \phi_2 \sigma_{t-1}^2 + \dots + \phi_p \sigma_{t-p}^2 + \theta_2 X_{t-2}^2 + \dots + \theta_q X_{t-q}^2.$$

This equation gives rise to the recursive equations for the ‘state vectors’ $Y_t = (\sigma_t^2, \dots, \sigma_{t-p+1}^2, X_{t-1}^2, \dots, X_{t-q+1}^2)^T$ given by

$$(9.5) \quad \begin{pmatrix} \sigma_t^2 \\ \sigma_{t-1}^2 \\ \sigma_{t-2}^2 \\ \vdots \\ \sigma_{t-p+1}^2 \\ X_{t-1}^2 \\ X_{t-2}^2 \\ \vdots \\ X_{t-q+1}^2 \end{pmatrix} = \begin{pmatrix} \phi_1 + \theta_1 Z_{t-1}^2 & \phi_2 & \dots & \phi_{p-1} & \phi_p & \theta_2 & \dots & \theta_{q-1} & \theta_q \\ 1 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ 0 & 1 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & 1 & 0 & 0 & \dots & 0 & 0 \\ Z_{t-1}^2 & 0 & \dots & 0 & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & \dots & 0 & 0 & 1 & \dots & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & 1 & 0 \end{pmatrix} \begin{pmatrix} \sigma_{t-1}^2 \\ \sigma_{t-2}^2 \\ \sigma_{t-3}^2 \\ \vdots \\ \sigma_{t-p}^2 \\ X_{t-2}^2 \\ X_{t-3}^2 \\ \vdots \\ X_{t-q}^2 \end{pmatrix} + \alpha e_1.$$

For A_t the (random!) matrix in this display and $b = \alpha e_1$ for e_1 the first unit vector, this recursion can be written $Y_t = A_t Y_{t-1} + b$. We can construct a GARCH process by first constructing a vector-valued process Y_t satisfying this recursive equation, and next defining σ_t^2 as the first coordinate of this process and finally setting $X_t = \sigma_t Z_t$.

We start with investigating second order stationary solutions. In the following theorem we consider given a martingale difference sequence Z_t satisfying (9.2), defined on a fixed probability space equipped with a given filtration $(\mathcal{F}_t: t \in \mathbb{Z})$. The first part of the theorem shows that a stationary GARCH process exists if and only if $\sum_j (\phi_j + \theta_j) < 1$. The last part shows essentially that the filtration may be reduced to the natural filtration of the GARCH process, without changing anything.

9.10 Theorem. *Let $\alpha > 0$, let $\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$ be nonnegative numbers, and let Z_t be a martingale difference sequence satisfying (9.2) relative to an arbitrary filtration \mathcal{F}_t .*

- (i) *There exists a stationary GARCH process $(X_t: t \in \mathbb{Z})$ such that $X_t = \sigma_t Z_t$, where $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$, if and only if $\sum_j (\phi_j + \theta_j) < 1$.*
- (ii) *This process is unique among the GARCH processes X_t with $X_t = \sigma_t Z_t$ that are bounded in L_2 .*

- (iii) This process satisfies $\sigma(X_t, X_{t-1}, \dots) = \sigma(Z_t, Z_{t-1}, \dots)$ for every t , and $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$ is $\sigma(X_{t-1}, X_{t-2}, \dots)$ -measurable.

Proof. By iterating (9.5) we find, for every $n \geq 1$,

$$(9.6) \quad Y_t = b + A_t b + A_t A_{t-1} b + \dots + A_t A_{t-1} \dots A_{t-n+1} b + A_t A_{t-1} \dots A_{t-n} Y_{t-n-1}.$$

If the last term on the right tends to zero as $n \rightarrow \infty$, then this gives

$$(9.7) \quad Y_t = b + \sum_{j=1}^{\infty} A_t A_{t-1} \dots A_{t-j+1} b.$$

We shall prove that this representation is indeed valid (with convergence of the series in probability) for the process Y_t corresponding to a GARCH process that is bounded in L_2 . Because the right side of the display is a given function of the Z_t , the uniqueness (ii) of such a GARCH process for a given process Z_t is then clear. To prove existence, as in (i), we shall reverse the argument: we use equation (9.7) to define a process Y_t , and next define processes σ_t and X_t as functions of Y_t and Z_t . We start by studying the random matrix products $A_t A_{t-1} \dots A_{t-n}$.

The expectation $A = EA_t$ of a single matrix is obtained by replacing the variable Z_{t-1}^2 in the definition of A_t by its expectation 1. Since $Z_t = X_t/\sigma_t$ is \mathcal{F}_t -measurable and $E(Z_t^2 | \mathcal{F}_{t-1}) = 1$ for every t , we can use the towering property of conditional expectations to see that the expectation of the product of the matrices is the product of the expectations: $EA_t A_{t-1} \dots A_{t-n} = A^{n+1}$.

The characteristic polynomial of the matrix A can (with some effort) be seen to be equal to

$$\det(A - zI) = (-z)^{p+q-1} \left(1 - \sum_{j=1}^r (\phi_j + \theta_j) z^{-j}\right).$$

If $\sum_j (\phi_j + \theta_j) < 1$, then the polynomial on the right has all its roots inside the unit circle, by Lemma 9.11. In other words, the spectral radius (the maximum of the moduli of the eigenvalues) of the operator A is then strictly smaller than 1. This implies that $\|A^n\|^{1/n} < c < 1$ for some constant c for all sufficiently large n and hence $\sum_{n=0}^{\infty} \|A^n\| < \infty$.

Combining the results of the last two paragraphs we see that $EA_t A_{t-1} \dots A_{t-n} = A^{n+1} \rightarrow 0$ as $n \rightarrow \infty$ if $\sum_j (\phi_j + \theta_j) < 1$. Because the matrices A_t possess nonnegative entries, this implies that the sequence $A_t A_{t-1} \dots A_{t-n}$ converges to zero in probability. If X_t is a GARCH process that is bounded in L_2 , then, in view of its definition, the corresponding vector-valued process Y_t is bounded in L_1 , and hence bounded in probability. In that case $A_t A_{t-1} \dots A_{t-n} Y_{t-n-1} \rightarrow 0$ in probability as $n \rightarrow \infty$, whence Y_t satisfies (9.7). This concludes the proof of the uniqueness (ii).

Under the assumption that $\sum_j (\phi_j + \theta_j) < 1$, the series on the right side of (9.7) converges in L_1 and almost surely. Thus we can use this equation to define a process Y_t from the given martingale difference series Z_t . Simple algebra on the infinite series shows

that $Y_t = A_t Y_{t-1} + b$ for every t . Clearly the coordinates of Y_t are nonnegative, whence we can define processes σ_t and X_t by

$$\sigma_t = \sqrt{Y_{t,1}}, \quad X_t = \sigma_t Z_t.$$

Because σ_t is $\sigma(Z_{t-1}, Z_{t-2}, \dots) \subset \mathcal{F}_{t-1}$ -measurable, we have that $E(X_t | \mathcal{F}_{t-1}) = \sigma_t E(Z_t | \mathcal{F}_{t-1}) = 0$ and $E(X_t^2 | \mathcal{F}_{t-1}) = \sigma_t^2 E(Z_t^2 | \mathcal{F}_{t-1}) = \sigma_t^2$. Furthermore, the process σ_t^2 satisfies the GARCH relation (9.1). Indeed, the first row of the matrix equation $Y_t = A_t Y_{t-1} + b$ expresses σ_t^2 into σ_{t-1}^2 and $Y_{t-1,2}, \dots, Y_{t-1,p+q-1}$, and the other rows permit to reexpress $Y_{t-1,2}, \dots, Y_{t-1,p+q-1}$ into variables σ_s^2 and X_s^2 so as to recover the equation (9.4). For instance, the second row gives that $Y_{t,2} = Y_{t-1,1} = \sigma_{t-1}^2$, and next the third row gives that $Y_{t,3} = Y_{t-1,2} = \sigma_{t-2}^2$. Similarly, the $p+1$ th row gives that $Y_{t,p+1} = Z_{t-1}^2 Y_{t-1,1} = Z_{t-1}^2 \sigma_{t-1}^2 = X_{t-1}^2$ by the definition of X_{t-1} . Finally the $p+2$ th to $p+q-1$ th rows give that $Y_{t,p+2} = Y_{t-1,p+1} = X_{t-2}^2$, $Y_{t,p+3} = Y_{t-1,p+2} = X_{t-3}^2$, etc. This concludes the proof that there exists a stationary solution as soon as $\sum_j (\phi_j + \theta_j) < 1$.

To see that the latter condition is necessary, we return to equation (9.6). If X_t is a stationary solution, then its conditional variance process σ_t^2 is integrable, and hence so is the process Y_t in (9.6). Taking the expectation of the left and right sides of this equation for $t = 0$ and remembering that all terms are nonnegative, we see that $\sum_{j=0}^n A^j b \leq E Y_0$, for every n . This implies that $A^n b \rightarrow 0$ as $n \rightarrow \infty$, or, equivalently $A^n e_1 \rightarrow 0$, where e_i is the i th unit vector. In view of the definition of A we see, recursively, that

$$\begin{aligned} A^n e_{p+q-1} &= A^{n-1} \theta_q e_1 \rightarrow 0, \\ A^n e_{p+q-2} &= A^{n-1} (\theta_{q-1} e_1 + e_{p+q-1}) \rightarrow 0, \\ &\vdots \\ A^n e_{p+1} &= A^{n-1} (\theta_2 e_1 + e_{p+2}) \rightarrow 0, \\ A^n e_p &= A^{n-1} \phi_p e_1 \rightarrow 0, \\ A^n e_{p-1} &= A^{n-1} (\phi_{p-1} e_1 + e_p), \\ &\vdots \\ A^n e_2 &= A^{n-1} (\phi_2 e_1 + e_3) \rightarrow 0. \end{aligned}$$

Therefore, the sequence A^n converges to zero. This can only happen if none of its eigenvalues is on or outside the unit disc. (If z is an eigenvalue of A with $|z| \geq 1$ and $c \neq 0$ a corresponding eigenvector, then $A^n c = z^n c$ does not converge to zero.) This was seen to be the case only if $\sum_{j=1}^r (\phi_j + \theta_j) < 1$.

This concludes the proof of (i) and (ii). For the proof of (iii) we first note that the matrices A_t , and hence the variables Y_t , are measurable functions of $(Z_{t-1}, Z_{t-2}, \dots)$. In particular, the variable σ_t^2 , which is the first coordinate of Y_t , is $\sigma(Z_{t-1}, Z_{t-2}, \dots)$ -measurable, so that the second assertion of (iii) follows from the first.

Because the variable $X_t = \sigma_t Z_t$ is a measurable transformation of (Z_t, Z_{t-1}, \dots) , it follows that $\sigma(X_t, X_{t-1}, \dots) \subset \sigma(Z_t, Z_{t-1}, \dots)$. To prove the converse, we note that the process $W_t = X_t^2 - \sigma_t^2$ is bounded in L_1 and satisfies the ARMA relation $(\phi - \theta)(B)X_t^2 = \alpha + \phi(B)W_t$, as in (9.3). Because ϕ has no roots on the unit disc, this relation

is invertible, whence $W_t = (1/\phi)(B)((\phi - \theta)(B)X_t^2 - \alpha)$ is a measurable transformation of X_t^2, X_{t-1}^2, \dots . Therefore $\sigma_t^2 = W_t + X_t^2$ and hence $Z_t = X_t/\sigma_t$ is $\sigma(X_t, X_{t-1}, \dots)$ -measurable. ■

9.11 Lemma. *If p_1, \dots, p_r are nonnegative real numbers, then the polynomial $p(z) = 1 - \sum_{j=1}^r p_j z^j$ possesses no roots on the complex unit disc if and only if $p(1) > 0$.*

Proof. Clearly $p(0) = 1 > 0$. If $p(1) \leq 0$, then by continuity the polynomial p must have a real root in the interval $(0, 1]$. On the other hand, if $p(1) > 0$, then by the triangle inequality $|p(z)| \geq 1 - \sum_j p_j |z|^j \geq 1 - \sum_j p_j = p(1) > 0$, for all z in the complex unit disc, whence p has no roots. ■

9.12 EXERCISE. Show that any GARCH process $X_t = \sigma_t Z_t$ satisfies

$$(9.8) \quad \sigma_t^2 = \alpha + (\phi_1 + \theta_1 Z_{t-1}^2) \sigma_{t-1}^2 + \dots + (\phi_r + \theta_r Z_{t-r}^2) \sigma_{t-r}^2.$$

This exhibits the process σ_t^2 as an auto-regressive process “with random coefficients” (the variables $\phi_i + \theta_i Z_{t-i}^2$) and “deterministic innovations” (the constant α). Write this equation in state space form with state vectors $Y_{t-1} = (\sigma_{t-1}^2, \dots, \sigma_{t-r}^2)$. Show that stationarity of X_t implies that Y_t satisfies (9.7) for appropriate random matrices A_t . [The mean $A = E A_t$ of the matrices is obtained by replacing the Z_t^2 by their expectations, and $\det(A - zI) = (-1)^r (z^r - \sum_{j=1}^r (\phi_j + \theta_j) z^{r-j})$.]

The proof of Theorem 9.10 hinges on the infinite series (9.7). The necessary and sufficient condition $\sum_j (\phi_j + \theta_j) < 1$ for stationarity arises because this is necessary for its convergence in L_1 . If the series converges in another (weaker) sense, then a GARCH process may still exist, albeit that it cannot have bounded second moments.

The series (9.7) involves products of random matrices A_t . Its convergence depends on the value of their *top Lyapounov exponent*, defined by

$$\gamma = \inf_{n \in \mathbb{N}} \frac{1}{n} E \log \|A_{-1} A_{-2} \cdots A_{-n}\|.$$

Here $\|\cdot\|$ may be any matrix norm (all matrix norms being equivalent). If the process Z_t is ergodic, for instance i.i.d., then we can apply Kingman’s subergodic theorem (see Theorem 7.17) to the process $\log \|A_{-1} A_{-2} \cdots A_{-n}\|$ to see that

$$\frac{1}{n} \log \|A_{-1} A_{-2} \cdots A_{-n}\| \rightarrow \gamma, \quad \text{a.s..}$$

This implies that the sequence of matrices $A_{-1} A_{-2} \cdots A_{-n}$ converges to zero almost surely as soon as $\gamma < 0$. The convergence is then exponentially fast and the series in (9.7) will converge.

Thus sufficient conditions for the existence of strictly stationary solutions to the GARCH equations can be given in terms of the top Lyapounov exponent of the random matrices A_t . This exponent is in general difficult to compute analytically, but it can easily be estimated numerically for a given sequence Z_t .

The setting is the same as in Theorem 9.10, except that we now also assume ergodicity of the ‘innovations’ Z_t . For instance, Z_t can be a given i.i.d. sequence of random variables with mean zero and unit variance and \mathcal{F}_t its natural filtration.

9.13 Theorem. Let $\alpha > 0$, let $\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$ be nonnegative numbers, and let Z_t be a strictly stationary, ergodic martingale difference series satisfying (9.2).

- (i) If the top Lyapounov coefficient of the random matrices A_t given by (9.5) is strictly negative, then there exists a strictly stationary GARCH process X_t such that $X_t = \sigma_t Z_t$, where $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$.
- (ii) If the sequence Z_t is i.i.d., then this condition is necessary.
- (iii) This process satisfies $\sigma(X_t, X_{t-1}, \dots) = \sigma(Z_t, Z_{t-1}, \dots)$ for every t , and $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$ is $\sigma(X_{t-1}, X_{t-2}, \dots)$ -measurable.

Proof. Let $b = \alpha e_1$, where e_i is the i th unit vector in \mathbb{R}^{p+q-1} . If γ' is strictly larger than the top Lyapounov exponent γ , then $\|A_t A_{t-1} \cdots A_{t-n+1}\| < e^{\gamma' n}$, eventually as $n \rightarrow \infty$, almost surely, and hence, eventually,

$$\|A_t A_{t-1} \cdots A_{t-n+1} b\| < e^{\gamma' n} \|b\|.$$

If $\gamma < 0$, then we may choose $\gamma' < 0$, and hence $\sum_n \|A_t A_{t-1} \cdots A_{t-n+1} b\| < \infty$ almost surely. Then the series on the right side of (9.7) converges almost surely and defines a process Y_t . We can then define processes σ_t and X_t by setting $\sigma_t = \sqrt{Y_{t,1}}$ and $X_t = \sigma_t Z_t$. That these processes satisfy the GARCH relation follows from the relations $Y_t = A_t Y_{t-1} + b$, as in the proof of Theorem 9.10. Being a fixed measurable transformation of (Z_t, Z_{t-1}, \dots) for each t , the process (σ_t, X_t) is strictly stationary.

By construction the variable X_t is $\sigma(Z_t, Z_{t-1}, \dots)$ -measurable for every t . To see that, conversely, Z_t is $\sigma(X_t, X_{t-1}, \dots)$ -measurable, we apply a similar argument as in the proof of Theorem 9.10, based on inverting the relation $(\phi - \theta)(B)X_t^2 = \alpha + \phi(B)W_t$, for $W_t = X_t^2 - \sigma_t^2$. Presently, the series X_t^2 and W_t are not necessarily integrable, but Lemma 9.14 below still allows to conclude that W_t is $\sigma(X_t^2, X_{t-1}^2, \dots)$ -measurable, provided that the polynomial ϕ has no zeros on the unit disc.

The matrix B obtained by replacing the variables Z_{t-1} and the numbers θ_j in the matrix A_t by zero is bounded above by A_t in a coordinatewise sense. By the nonnegativity of the entries this implies that $B^n \leq A_0 A_{-1} \cdots A_{-n+1}$ and hence $B^n \rightarrow 0$. This can happen only if all eigenvalues of B are inside the unit circle. Now

$$\det(B - zI) = (-z)^{p+q-1} \phi(1/z).$$

Thus z is a zero of ϕ if and only if z^{-1} is an eigenvalue of B . We conclude that ϕ has no zeros on the unit disc.

Finally, we show the necessity of the top Lyapounov exponent being negative if Z_t is i.i.d.. If there exists a strictly stationary solution to the GARCH equations, then, by (9.6) and the nonnegativity of the coefficients, $\sum_{j=1}^n A_0 A_{-1} \cdots A_{-n+1} b \leq Y_0$ for every n , and hence $A_0 A_{-1} \cdots A_{-n+1} b \rightarrow 0$ as $n \rightarrow \infty$, almost surely. By the form of b this is equivalent to $A_0 A_{-1} \cdots A_{-n+1} e_1 \rightarrow 0$. Using the structure of the matrices A_t we next see that $A_0 A_{-1} \cdots A_{-n+1} \rightarrow 0$ in probability as $n \rightarrow \infty$, by an argument similar as in the proof of Theorem 9.10. Because the matrices A_t are independent and the event where $A_0 A_{-1} \cdots A_{-n+1} \rightarrow 0$ is a tail event, this event must have probability one. It can be shown that this is possible only if the top Lyapounov exponent of the matrices A_t is negative.^b ■

^b See Bougerol (), Lemma ?.

9.14 Lemma. Let ϕ be a polynomial without roots on the unit disc and let X_t be a time series that is bounded in probability. If $Z_t = \phi(B)X_t$ for every t , then X_t is $\sigma(Z_t, Z_{t-1}, \dots)$ -measurable.

Proof. Because $\phi(0) \neq 0$ by assumption, we can assume without loss of generality that ϕ possesses intercept 1. If ϕ is of degree 0, then $X_t = Z_t$ for every t and the assertion is certainly true. We next proceed by induction on the degree of ϕ . If ϕ is of degree $p \geq 1$, then we can write it as $\phi(z) = (1 - \phi z)\phi_{p-1}(z)$ for a polynomial ϕ_{p-1} of degree $p-1$ and a complex number ϕ with $|\phi| < 1$. The series $Y_t = (1 - \phi B)X_t$ is bounded in probability and $\phi_{p-1}(B)Y_t = Z_t$, whence Y_t is $\sigma(Z_t, Z_{t-1}, \dots)$ -measurable, by the induction hypothesis. By iterating the relation $X_t = \phi X_{t-1} + Y_t$, we find that $X_t = \phi^n X_{t-n} + \sum_{j=0}^{n-1} \phi^j Y_{t-j}$. Because the sequence X_t is uniformly tight and $\phi^n \rightarrow 0$, the sequence $\phi^n X_{t-n}$ converges to zero in probability as $n \rightarrow \infty$. Hence X_t is the limit in probability of a sequence that is $\sigma(Y_t, Y_{t-1}, \dots)$ -measurable and hence is $\sigma(Z_t, Z_{t-1}, \dots)$ -measurable. This implies the result. ■

** **9.15 EXERCISE.** In the preceding lemma the function $\psi(z) = 1/\phi(z)$ possesses a power series representation $\psi(z) = \sum_{j=0}^{\infty} \psi_j z^j$ on a neighbourhood of the unit disc. Is it true under the conditions of the lemma that $X_t = \sum_{j=0}^{\infty} \psi_j Z_{t-j}$, where the series converges (at least) in probability?

9.16 Example. For the GARCH(1,1) process the random matrices A_t given by (9.5) reduce to the random variables $\phi_1 + \theta_1 Z_{t-1}^2$. The top Lyapounov exponent of these random (1×1) matrices is equal to $E \log(\phi_1 + \theta_1 Z_t^2)$. This number can be written as an integral relative to the distribution of Z_t , but in general is not easy to compute analytically. Figure 9.3 shows the points (ϕ_1, θ_1) for which a strictly stationary GARCH(1,1) process exists in the case of Gaussian innovations Z_t . It also shows the line $\phi_1 + \theta_1 = 1$, which is the boundary line for existence of a stationary solution. □

9.1.3 Stability and Persistence

Lemma 9.3 gives a simple recipe for constructing a GARCH process, at least on the positive time set. In the preceding section it was seen that a (strictly) stationary version exists only for certain parameter values, and then is unique. Clearly this stationary solution is obtained by the recipe of Lemma 9.3 only if the initial values in this lemma are chosen according to the stationary distribution.

In the following theorem we show that the effect of a “nonstationary” initialization wears off as $t \rightarrow \infty$ and the process will approach stationarity, *provided that a stationary solution exists*. This is true both for L_2 -stationarity and strict stationarity, under the appropriate conditions on the coefficients.

9.17 Theorem. For a number $\alpha > 0$ and nonnegative numbers $\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$ and a martingale difference series Z_t satisfying (9.2), let $X_t = \sigma_t Z_t$ and $\tilde{X}_t = \tilde{\sigma}_t Z_t$ be two solutions to the GARCH equation.

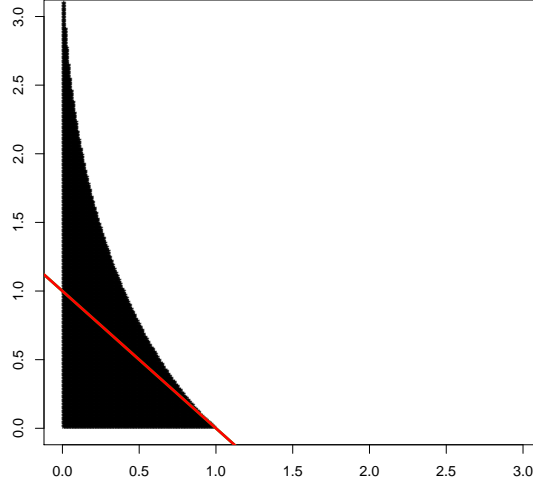

Figure 9.3. The shaded area gives all points (ϕ, θ) where $E \log(\phi + \theta Z^2) < 0$ for a standard normal variable Z . For each point in this area a strictly stationary GARCH process with Gaussian innovations exists. This process is stationary if and only if (ϕ, θ) falls under the line $\phi + \theta = 1$, which is also indicated.

- (i) If $\sum_j (\phi_j + \theta_j) < 1$ and X_t and \tilde{X}_t are square-integrable, then $X_t - \tilde{X}_t$ converges to zero in L_2 as $t \rightarrow \infty$.
- (ii) If the top Lyapounov exponent of the matrices A_t in (9.5) is negative, then $X_t - \tilde{X}_t$ converges to zero in probability as $t \rightarrow \infty$.

Proof. From the two given GARCH processes X_t and \tilde{X}_t define processes Y_t and \tilde{Y}_t as indicated preceding the statement of Theorem 9.13. These processes satisfy (9.6) for the matrices A_t given in (9.5). Choosing $n = t - 1$ and taking differences we see that

$$Y_t - \tilde{Y}_t = A_t A_{t-1} \cdots A_1 (Y_0 - \tilde{Y}_0).$$

If the top Lyapounov exponent of the matrices A_t is negative, then the norm of the right side can be bounded, almost surely for sufficiently large t , by $e^{\gamma' t} \|Y_0 - \tilde{Y}_0\|$ for some number $\gamma' < 0$. This follows from the subergodic theorem, as before (even though this time the matrix product grows on its left side). This converges to zero as $t \rightarrow \infty$, implying that $\sigma_t^2 - \tilde{\sigma}_t^2 = Y_{t,1} - \tilde{Y}_{t,1} \rightarrow 0$ almost surely as $t \rightarrow \infty$. Hence $\sigma_t - \tilde{\sigma}_t \rightarrow 0$ almost surely, and $X_t - \tilde{X}_t = (\sigma_t - \tilde{\sigma}_t)Z_t \rightarrow 0$ in probability, because Z_t is bounded in probability. This concludes the proof of (ii).

Under the condition of (i), the spectral radius of the matrix $A = EA_t$ is strictly smaller than 1 and hence $\|A^n\| \rightarrow 0$. By the nonnegativity of the entries of the matrices A_t the absolute values of the coordinates of the vectors $Y_t - \tilde{Y}_t$ are bounded above by the coordinates of the vector $A_t A_{t-1} \cdots A_1 W_0$, for W_0 the vector obtained by replacing the coordinates of $Y_0 - \tilde{Y}_0$ by their absolute values. By the independence of the matrices

A_t and vector W_0 , the expectation of $A_t A_{t-1} \cdots A_1 W_0$ is bounded by $A^t E W_0$, which converges to zero. Because $\sigma_t^2 = Y_{t,1}$ and $X_t = \sigma_t Z_t$, this implies that, as $t \rightarrow \infty$,

$$E|X_t - \tilde{X}_t|^2 = E|\sigma_t - \tilde{\sigma}_t|^2 Z_t^2 \leq E|\sigma_t^2 - \tilde{\sigma}_t^2| \rightarrow 0.$$

In the last step we use nonnegativity of the volatility, and the inequality $|x-y|^2 \leq |x^2-y^2|$ for nonnegative numbers x, y . This concludes the proof. ■

The preceding theorem exhibits two different notions of “persistence” of the initial values to a GARCH series. If the condition for strict stationarity are satisfied, then any GARCH series will tend to the stationary solution and hence the influence of the initial values wears off as time goes to infinity. The initial values are not “persistent” in this case. If the stronger condition $\sum_j (\phi_j + \theta_j) < 1$ for L_2 -stationarity holds, then the process will also approach stationarity in the stronger L_2 -sense.

It is a little counter-intuitive that for parameter values for which the top Lyapounov exponent is negative, but $\sum_j (\phi_j + \theta_j) \geq 1$, the initial values are persistent in an L_2 -sense. There is no stationary GARCH process in this situation, and hence the strictly stationary GARCH process must have infinite variance. An arbitrary GARCH process will approach the strictly stationary process and therefore its variance must tend to infinity (see the exercise below). We shall see in the next section that the initialization then may influence the way that the second moments explode. (Depending on the initialization the variances may be finite or infinite. The conditional variances are finite by assumption.)

The case that $\sum_j (\phi_j + \theta_j) = 1$ is often viewed as having particular interest and is referred to as *integrated GARCH* or IGARCH. Many financial time series yield GARCH fits that are close to IGARCH.

9.18 EXERCISE. Suppose that the time series \tilde{X}_t is strictly stationary with infinite second moments and $X_t - \tilde{X}_t \rightarrow 0$ in probability as $t \rightarrow \infty$. Show that $E X_t^2 \rightarrow \infty$.

9.1.4 Prediction

As it is a martingale difference process, a GARCH process does not allow nontrivial predictions of its mean values. However, it is of interest to predict the conditional variances σ_t^2 , or equivalently the process of squares X_t^2 . Predictions based on the infinite past \mathcal{F}_t can be obtained using the auto-regressive representation $Y_t = A_t Y_{t-1} + b$ given in (9.5) and used in the proofs of Theorems 9.13 and 9.10, for $Y_t = (\sigma_t^2, \dots, \sigma_{t-p+1}^2, X_{t-1}^2, \dots, X_{t-q+1}^2)^T$. The vector Y_{t-1} is \mathcal{F}_{t-2} -measurable, and the matrix A_t depends on Z_{t-1} only, with $A = E(A_t | \mathcal{F}_{t-2})$ independent of t . It follows that

$$E(Y_t | \mathcal{F}_{t-2}) = E(A_t | \mathcal{F}_{t-2}) Y_{t-1} + b = A Y_{t-1} + b.$$

By iterating this equation we find that, for $h > 1$,

$$(9.9) \quad E(Y_t | \mathcal{F}_{t-h}) = A^{h-1} Y_{t-h+1} + \sum_{j=0}^{h-2} A^j b.$$

As σ_t^2 is the first coordinate of Y_t , this equation gives in particular the predictions for the volatility, based on the infinite past. If $\sum_j(\phi_j + \theta_j) < 1$, then the spectral radius of the matrix A is strictly smaller than 1, and both terms on the right converge to zero at an exponential rate, as $h \rightarrow \infty$. In this case the potential of predicting the conditional variance process is limited to the very near future. The case that $\sum_j(\phi_j + \theta_j) \geq 1$ is more interesting, as is illustrated by the following example.

9.19 Example (GARCH(1,1)). For a GARCH(1,1) process the vector Y_t is equal to σ_t^2 and the matrix A reduces to the number $\phi_1 + \theta_1$. The general equation (9.9) can be rewritten in the form

$$(9.10) \quad E(X_{t+h}^2 | \mathcal{F}_t) = E(\sigma_{t+h}^2 | \mathcal{F}_t) = (\phi_1 + \theta_1)^{h-1} \sigma_{t+1}^2 + \alpha \sum_{j=0}^{h-2} (\phi_1 + \theta_1)^j.$$

For $\phi_1 + \theta_1 < 1$ the first term on the far right converges to zero as $h \rightarrow \infty$, indicating that information at the present time t does not help to predict the conditional variance process in the “infinite future”. On the other hand, if $\phi_1 + \theta_1 \geq 1$ and $\alpha > 0$ then both terms on the far right side contribute positively as $h \rightarrow \infty$. If $\phi_1 + \theta_1 = 1$, then the contribution of the term $(\phi_1 + \theta_1)^{h-1} \sigma_{t+1}^2 = \sigma_t^2$ is constant, and hence tends to zero relative to the nonrandom term (which becomes $\alpha(h-1) \rightarrow \infty$), as $h \rightarrow \infty$. If $\phi_1 + \theta_1 > 1$, then the contributions of the two terms are of the same order. In both cases the volatility σ_t^2 persists into the future, although in the first case its relative influence on the prediction dwindles. If $\phi_1 + \theta_1 > 1$, then the value σ_t^2 is particularly “persistent”; this happens even if the time series tends to (strict) stationarity in distribution. \square

9.20 EXERCISE. Suppose that $\sum_j(\phi_j + \theta_j) < 1$ and let X_t be a stationary GARCH process. Show that $E(X_{t+h}^2 | \mathcal{F}_t) \rightarrow EX_t^2$ as $h \rightarrow \infty$. [Hint: use (9.9).]

* 9.2 Linear GARCH with Leverage and Power GARCH

Fluctuations of foreign exchange rates tend to be symmetric, in view of the two-sided nature of the foreign exchange market. However, it is an empirical finding that for asset prices the current returns and future volatility are negatively correlated. For instance, a crash (small returns) in the stock market is often followed by large volatility.

A linear GARCH model is not able to capture this type of asymmetric relationship, because it models the volatility as a function of the squares of the past returns. One attempt to allow for asymmetry is to replace the GARCH equation (9.1) by

$$\sigma_t^2 = \alpha + \phi_1 \sigma_{t-1}^2 + \cdots + \phi_p \sigma_{t-p}^2 + \theta_1 (|X_{t-1}| + \gamma_1 X_{t-1})^2 + \cdots + \theta_q (|X_{t-q}| + \gamma_q X_{t-q})^2.$$

This reduces to the ordinary GARCH equation if the *leverage coefficients* γ_i are set equal to zero. If these coefficients are negative, then a positive deviation of the process

X_t contributes to lower volatility in the near future, and conversely (see Figure 9.4). A time series with conditional variances of this type is called *GARCH with leverage*.

A *power GARCH* model is obtained by replacing the squares in the preceding display by other powers.

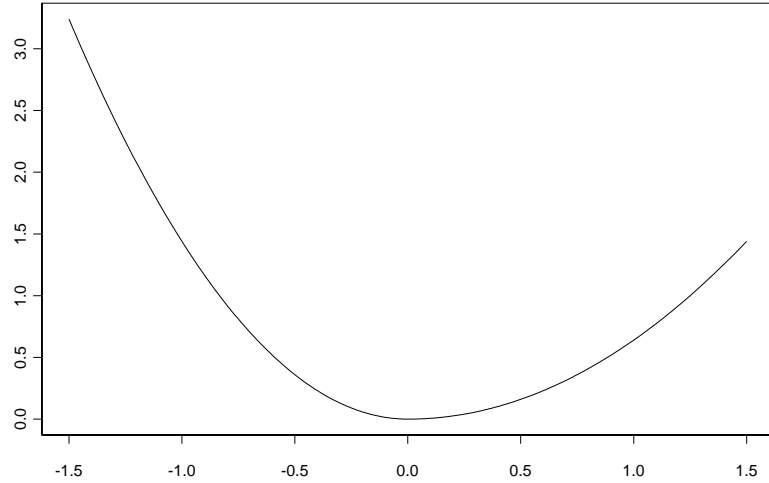

Figure 9.4. The function $x \mapsto (|x| + \gamma x)^2$ for $\gamma = -0.2$.

* 9.3 Exponential GARCH

The exponential GARCH, or EGARCH, model differs significantly from the GARCH models described so far. It retains the basic set-up of a process of the form $X_t = \sigma_t Z_t$ for a martingale difference sequence Z_t satisfying (9.2) and an \mathcal{F}_{t-1} -adapted process σ_t , but replaces the GARCH equation by

$$\log \sigma_t^2 = \alpha + \phi_1 \log \sigma_{t-1}^2 + \cdots + \phi_p \log \sigma_{t-p}^2 + \theta_1 (|Z_{t-1}| + \gamma_1 Z_{t-1}) + \cdots + \theta_q (|Z_{t-q}| + \gamma_q Z_{t-q}).$$

The inclusion of both the variables Z_t and their absolute values and the transformation to the logarithmic scale attempts to capture the leverage effect. An advantage of modelling the logarithm of the volatility is that the parameters of the model need not be restricted to be positive.

Because the EGARCH model specifies the log volatility directly in terms of the noise process Z_t and its own past, its definition is less recursive than the ordinary GARCH definition, and easier to handle. In particular, for fixed and identical leverage coefficients

$\gamma_i = \gamma$ the EGARCH equation describes the log volatility process $\log \sigma_t^2$ as a regular ARMA process driven by the noise process $|Z_t| + \gamma Z_t$, and we may use the theory for ARMA processes to study its properties. In particular, if the roots of the polynomial $\phi(z) = 1 - \phi_1 z - \cdots - \phi_p z^p$ are outside the unit circle, then there exists a stationary solution $\log \sigma_t^2$ that is measurable relative to the σ -field generated by the process Z_{t-1} . If the process Z_t is strictly stationary, then so is the stationary solution $\log \sigma_t^2$ and so is the EGARCH process $X_t = \sigma_t Z_t$.

* 9.4 GARCH in Mean

By its definition a GARCH process is a white noise process, and thus can be a useful candidate to drive another process. For instance, an observed process Y_t could be assumed to satisfy the ARMA equation

$$\bar{\phi}(B)Y_t = \bar{\theta}(B)X_t,$$

for X_t a GARCH process, relative to (other) polynomials ϕ and θ (unrelated to $\bar{\phi}$ and $\bar{\theta}$). One then says that Y_t is “ARMA in the mean” and “GARCH in the variance”, or that Y_t is an ARMA-GARCH series. Results on ARMA processes that hold for any driving white noise process will clearly also hold in the present case, where the white noise process is a GARCH process.

9.21 EXERCISE. Let X_t be a stationary GARCH process relative to polynomials ϕ and θ and let the time series Y_t be the unique stationary solution to the equation $\bar{\phi}(B)Y_t = \bar{\theta}(B)X_t$, for $\bar{\phi}$ and $\bar{\theta}$ polynomials that have all their roots outside the unit disc. Let \mathcal{F}_t be the filtration generated by Y_t . Show that $\text{var}(Y_t | \mathcal{F}_{t-1}) = \text{var}(X_t | X_{t-1}, X_{t-2}, \dots)$ almost surely.

It has been found useful to go a step further and let also the conditional variance of the driving GARCH process appear in the mean model for the process Y_t . Thus given a GARCH process X_t with conditional variance process $\sigma_t^2 = \text{var}(X_t | \mathcal{F}_{t-1})$ it is assumed that $Y_t = f(\sigma_t, X_t)$ for a fixed function f . The function f is assumed known up to a number of parameters. For instance,

$$\begin{aligned}\bar{\phi}(B)Y_t &= \psi \sigma_t + \bar{\theta}(B)X_t, \\ \bar{\phi}(B)Y_t &= \psi \sigma_t^2 + \bar{\theta}(B)X_t, \\ \bar{\phi}(B)Y_t &= \psi \log \sigma_t^2 + \bar{\theta}(B)X_t.\end{aligned}$$

These models are known as *GARCH-in-mean*, or GARCH-M models.

10

State Space Models

A time series or discrete time stochastic process X_t is *Markov* if the conditional distribution of X_{t+1} given the “past” values X_t, X_{t-1}, \dots depends on the “present” value X_t only, for every t . The evolution of a Markov process can be pictured as a sequence of moves in a “state space”, where at each time t the process chooses a new state X_{t+1} according to a random mechanism based only on the current state X_t , and not on the past evolution. The current state thus contains all necessary information to determine the future.

Markov structure obviously facilitates prediction, since only the current state is needed to predict the future. It also permits a simple factorization of the likelihood, which aids in defining and analyzing statistical procedures.

Markov structure can be created in any time series by redefining the states of the series to incorporate enough past information. The “present state” should contain all information that is relevant for the next state. In fact, given an arbitrary time series X_t , the process $\tilde{X}_t = (X_t, X_{t-1}, \dots)$ is Markov. However, the high complexity of the state space of the process \tilde{X}_t offsets the advantages of the Markov property.

General *state space models* take the idea of states that contain the relevant information as a basis, but go beyond Markov models. They typically consist of a specification of a Markov process together with a process of ‘observable outputs’. Although they come from a different background, *hidden Markov models* are almost identical structures.

The showpiece of state space modelling is the Kalman filter. This is an algorithm to compute linear predictions for certain linear state space models, under the assumption that the parameters of the system are known. Because the formulas for the predictors, which are functions of the parameters and the outputs, can in turn be used to set up estimating equations for the parameters, the Kalman filter is also important for statistical analysis. We start discussing parameter estimation in Chapter 11.

10.1 Example (AR(1)). A causal, stationary AR(1) process with i.i.d. innovations Z_t is a Markov process: the “future value” $X_{t+1} = \phi X_t + Z_{t+1}$ given the “past values” X_1, \dots, X_t depends on the “present value” X_t only. Specifically, the conditional density

of X_{t+1} is given by

$$p_{X_{t+1}|X_1,\dots,X_t}(x) = p_Z(x - \phi X_t).$$

The assumption of causality ensures that Z_{t+1} is independent of X_1, \dots, X_t . The Markov structure allows to factorize the density of (X_1, \dots, X_n) , as

$$p_{X_1,\dots,X_n}(X_1, \dots, X_n) = \prod_{t=2}^n p_Z(X_t - \phi X_{t-1}) p_{X_1}(X_1).$$

This expression as a function of the unknown parameter ϕ is the likelihood for the model. \square

10.2 EXERCISE. How can a causal $AR(p)$ process be forced into Markov form? Give a precise argument. Is “causal” needed?

10.1 Hidden Markov Models and State Spaces

A *hidden Markov model* consists of a Markov chain, but rather than the state at time t , we observe an “output” variable, which is generated by a mechanism which depends on the state. This is illustrated in Figure 10.1, where the sequence \dots, X_1, X_2, \dots depicts a Markov chain, and \dots, Y_1, Y_2, \dots are the outputs at times $1, 2, \dots$. It is assumed that given the state sequence \dots, X_1, X_2, \dots , the outputs \dots, Y_1, Y_2, \dots are independent, and the conditional distribution of Y_t given the states depends on X_t only. Thus the arrows in the picture indicate dependence relationships.

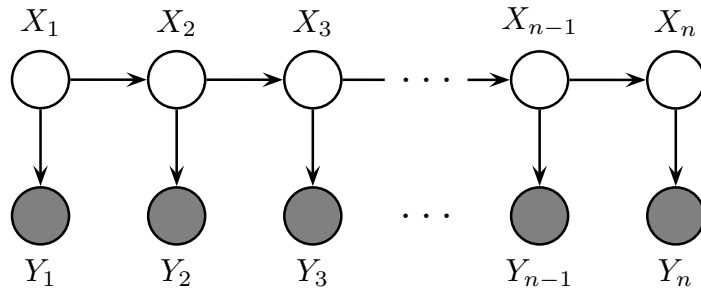

Figure 10.1. Hidden Markov model. The variables X_1, \dots, X_n form a Markov chain. The variables Y_1, \dots, Y_n are conditionally independent given this chain, with the conditional marginal distribution of Y_i depending on X_i only. Only the variables Y_1, \dots, Y_n are observed.

The probabilistic properties of a hidden Markov process are simple. For instance, the joint sequence (X_t, Y_t) can be seen to be Markovian, and we can easily write down the joint density of the variables $(X_1, Y_1, X_2, Y_2, \dots, X_n, Y_n)$ as

$$p(x_1)p(x_2|x_1) \times \cdots \times p(x_n|x_{n-1})p(y_1|x_1) \times \cdots \times p(y_n|x_n).$$

(Here, as later on in the chapter, we abuse notation by writing the conditional density of a variable Y given a variable X as $p(y|x)$ and a marginal density of X as $p(x)$, thus using the symbol p for any density function, leaving it to the arguments to reveal which density it is.) The difficulty is to do statistics in the case where *only* the outputs Y_1, \dots, Y_n are observed. Typical aims are to estimate parameters of the underlying distribution, and to compute “best guesses” of the unobserved states given the observed outputs.

Many *state space models* are hidden Markov models, although they are often described in a different manner. Given an “initial state” X_0 , “disturbances” V_1, W_1, V_2, \dots and functions f_t and g_t , processes X_t and Y_t are defined recursively by, for $t = 1, 2, \dots$,

$$(10.1) \quad \begin{aligned} X_t &= f_t(X_{t-1}, V_t), \\ Y_t &= g_t(X_t, W_t). \end{aligned}$$

We refer to X_t as the “state” at time t and to Y_t as the “output”. The state process X_t can be viewed as primary and evolving in the background, describing the consecutive states of a system in time. At each time t the system is “measured”, resulting in the observed output Y_t .

If the sequence X_0, V_1, V_2, \dots consists of independent variables, then the state process X_t is a Markov chain. If, moreover, the variables $X_0, V_1, W_1, V_2, W_2, V_3, \dots$ are independent, then for every t given the state X_t the output Y_t is conditionally independent of the states X_0, X_1, \dots and outputs $(Y_s: s \neq t)$. Then the state space model becomes a hidden Markov model. Conversely, any hidden Markov model arises in this form.

10.3 Lemma. *If $X_0, V_1, W_1, V_2, W_2, V_3, \dots$ are independent random variables, then the pair of sequences X_t and Y_t defined in (10.1) forms a hidden Markov model: the sequence X_1, X_2, \dots forms a Markov chain, the variables Y_1, Y_2, \dots are conditionally independent given X_0, X_1, X_2, \dots , and Y_t is conditionally independent of $(X_s: s \neq t)$ given X_t , for every t . Conversely, every hidden Markov model with state and output variables X_t and Y_t in Polish spaces can be realized in the form (10.1) for some sequence of independent random variables $X_0, V_1, W_1, V_2, W_2, V_3, \dots$ and measurable functions f_t and g_t .*

Proof. Any conditional distribution R of variables with values in Polish spaces (i.e. Markov kernel $(x, B) \mapsto R(B|x)$) from a Polish space D_1 into another Polish space D_2 can be represented as the distribution of $h(x, U)$ for a measurable map $h: D_1 \times [0, 1] \rightarrow D_2$, and a uniform random variable U (i.e. $R(x, B) = P(h(x, U) \in B)$). We apply this to the conditional laws of X_t given X_{t-1} and of Y_t given X_t to find functions f_t such that $X_t = f_t(X_{t-1}, V_t)$ and g_t such that $Y_t = g_t(X_t, W_t)$, where the variables V_t and W_t can be chosen independent and uniformly distributed. ■

The variables V_t and W_t are never observed, and in the state space model (10.1) are never observed, and typically the state process X_t is not either. At time t we only observe the output Y_t . For this reason the process Y_t is also referred to as the *measurement process*. The second equation in the display (10.1) is called the *measurement equation*, while the first is the *state equation*. Inference might be directed at estimating parameters attached to the functions f_t or g_t , to the distribution of the errors or to the initial state, and/or on predicting or reconstructing the states X_t from the observed outputs Y_1, \dots, Y_n . Predicting or reconstructing the state sequence is referred to as “filtering” or “smoothing”.

For linear functions f_t and g_t and vector-valued states and outputs the state space model can without loss of generality be written in the form

$$(10.2) \quad \begin{aligned} X_t &= F_t X_{t-1} + V_t, \\ Y_t &= G_t X_t + W_t. \end{aligned}$$

The matrices F_t and G_t are often postulated to be independent of t . In this linear state space model the analysis usually concerns linear predictions, and then a common assumption is that the vectors $X_0, V_1, W_1, V_2, \dots$ are uncorrelated. If F_t is independent of t and the vectors V_t form a white noise process, then the series X_t is a VAR(1) process.

Because state space models are easy to handle, it is of interest to represent a given observable time series Y_t as the output of a state space model. This entails finding a state space, a state process X_t , and a corresponding state space model with the given series Y_t as output. It is particularly attractive to find a linear state space model. Such a *state space representation* is definitely not unique. An important issue in systems theory is to find a (linear) state space representation of minimal dimension.

10.4 Example (State space representation ARMA). Let Y_t be a stationary, causal ARMA(p, q) process satisfying $\phi(B)Y_t = \theta(B)Z_t$ for an i.i.d. process Z_t . Then the AR(p) process $X_t = (1/\phi)(B)Z_t$ is related to Y_t through $Y_t = \theta(B)X_t$. Thus if $r \geq (p-1) \vee q$ and we pad the set of coefficients of the polynomials ϕ or θ with zeros to increase their numbers to r and $r+1$, if necessary, then

$$\begin{aligned} Y_t &= (\theta_0, \dots, \theta_r) \begin{pmatrix} X_t \\ \vdots \\ X_{t-r} \end{pmatrix}, \\ \begin{pmatrix} X_t \\ X_{t-1} \\ \vdots \\ X_{t-r} \end{pmatrix} &= \begin{pmatrix} \phi_1 & \phi_2 & \cdots & \phi_r & \phi_{r+1} \\ 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \begin{pmatrix} X_{t-1} \\ X_{t-2} \\ \vdots \\ X_{t-r-1} \end{pmatrix} + \begin{pmatrix} Z_t \\ 0 \\ \vdots \\ 0 \end{pmatrix}. \end{aligned}$$

This is a linear state space representation (10.2) with state vector (X_t, \dots, X_{t-r}) , and matrices F_t and G_t , that are independent of t . Under causality the innovations $V_t = (Z_t, 0, \dots, 0)$ are orthogonal to the past X_t and Y_t ; the innovations W_t as in (10.2) are identically zero. The state vectors are typically unobserved, except when θ is of degree

zero. (If the ARMA process is invertible and the coefficients of θ are known, then the states can be reconstructed from the infinite past through the relation $X_t = (1/\theta)(B)Y_t$.)

In the present representation the state-dimension of the ARMA(p, q) process is $r + 1 = \max(p, q + 1)$. By using a more complicated noise process it is possible to represent an ARMA(p, q) process in dimension $\max(p, q)$, but this difference appears not to be very important.[#] \square

10.5 EXERCISE. Find a state space representation of dimension $p \vee q$.

10.6 Example (State space representation ARIMA). Consider a time series Z_t whose differences $Y_t = \nabla Z_t$ satisfy the linear state space model (10.2) for a state sequence X_t . Writing $Z_t = Y_t + Z_{t-1} = G_t X_t + W_t + Z_{t-1}$, we obtain that

$$\begin{pmatrix} X_t \\ Z_{t-1} \end{pmatrix} = \begin{pmatrix} F_t & 0 \\ G_{t-1} & 1 \end{pmatrix} \begin{pmatrix} X_{t-1} \\ Z_{t-2} \end{pmatrix} + \begin{pmatrix} V_t \\ W_{t-1} \end{pmatrix},$$

$$Z_t = (G_t \ 1) \begin{pmatrix} X_t \\ Z_{t-1} \end{pmatrix} + W_t.$$

We conclude that the time series Z_t possesses a linear state space representation, with states of one dimension higher than the states of the original series.

A drawback of the preceding representation is that the error vectors (V_t, W_{t-1}, W_t) are not necessarily uncorrelated if the error vectors (V_t, W_t) in the system with outputs Y_t have this property. In the case that Z_t is an ARIMA($p, 1, q$) process, we may use the state representation of the preceding example for the ARMA(p, q) process Y_t , which has errors $W_t = 0$, and this disadvantage does not arise. Alternatively, we can avoid this problem by using another state space representation. For instance, we can write

$$\begin{pmatrix} X_t \\ Z_t \end{pmatrix} = \begin{pmatrix} F_t & 0 \\ G_t F_t & 1 \end{pmatrix} \begin{pmatrix} X_{t-1} \\ Z_{t-1} \end{pmatrix} + \begin{pmatrix} V_t \\ G_t V_t + W_t \end{pmatrix},$$

$$Z_t = (0 \ 1) \begin{pmatrix} X_t \\ Z_t \end{pmatrix}.$$

This illustrates that there may be multiple possibilities to represent a time series as the output of a (linear) state space model.

The preceding can be extended to general ARIMA(p, d, q) models. If $Y_t = (1-B)^d Z_t$, then $Z_t = Y_t - \sum_{j=1}^d \binom{d}{j} (-1)^j Z_{t-j}$. If the process Y_t can be represented as the output of a state space model with state vectors X_t , then Z_t can be represented as the output of a state space model with the extended states $(X_t, Z_{t-1}, \dots, Z_{t-d})$, or, alternatively, $(X_t, Z_t, \dots, Z_{t-d+1})$. \square

10.7 Example (Stochastic linear trend). A time series with a linear trend could be modelled as $Y_t = \alpha + \beta t + W_t$ for constants α and β , and a stationary process W_t (for instance an ARMA process). This restricts the nonstationary part of the time series to

[#] See e.g. Brockwell and Davis, p469–471.

a deterministic component, which may be unrealistic. An alternative is the *stochastic linear trend model* described by

$$\begin{pmatrix} A_t \\ B_t \end{pmatrix} = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} A_{t-1} \\ B_{t-1} \end{pmatrix} + V_t, \\ Y_t = A_t + W_t.$$

The stochastic processes (A_t, B_t) and noise processes (V_t, W_t) are unobserved. This state space model contains the deterministic linear trend model as the degenerate case where $V_t \equiv 0$, so that $B_t \equiv B_0$ and $A_t \equiv A_0 + B_0 t$.

The state equations imply that $\nabla A_t = B_{t-1} + V_{t,1}$ and $\nabla B_t = V_{t,2}$, for $V_t = (V_{t,1}, V_{t,2})^T$. Taking differences on the output equation $Y_t = A_t + W_t$ twice, we find that

$$\nabla^2 Y_t = \nabla B_{t-1} + \nabla V_{t,1} + \nabla^2 W_t = V_{t,2} + \nabla V_{t,1} + \nabla^2 W_t.$$

If the process (V_t, W_t) is a white noise process, then the auto-correlation function of the process on the right vanishes for lags bigger than 2 (the polynomial $\nabla^2 = (1 - B)^2$ being of degree 2). Thus the right side is an MA(2) process, whence the process Y_t is an ARIMA(0,2,2) process. \square

* **10.8 Example (Structural models).** Besides a trend we may suspect that a given time series shows a seasonal effect. One possible parametrization of a deterministic seasonal effect with S seasons is the function

$$(10.3) \quad t \mapsto \gamma_0 + \sum_{s=1}^{\lfloor S/2 \rfloor} \left(\gamma_s \cos(\lambda_s t) + \delta_s \sin(\lambda_s t) \right), \quad \lambda_s = \frac{2\pi s}{S}, \quad s = 1, \dots, \lfloor S/2 \rfloor.$$

By appropriate choice of the parameters γ_s and δ_s this function is able to adapt to any periodic function on the integers with period S . (See Exercise 10.10. If S is even, then the “last” sinus function $t \mapsto \sin(\lambda_{S/2} t)$ vanishes, and the coefficient δ_s is irrelevant. There are always S nontrivial terms in the sum.) We could add this deterministic function to a given time series model in order to account for seasonality. Again it may not be realistic to require the seasonality a-priori to be deterministic. An alternative is to replace the fixed function $s \mapsto (\gamma_s, \delta_s)$ by the time series defined by

$$\begin{pmatrix} \gamma_{s,t} \\ \delta_{s,t} \end{pmatrix} = \begin{pmatrix} \cos \lambda_s & \sin \lambda_s \\ \sin \lambda_s & -\cos \lambda_s \end{pmatrix} \begin{pmatrix} \gamma_{s,t-1} \\ \delta_{s,t-1} \end{pmatrix} + V_{s,t}.$$

An observed time series may next have the form

$$Y_t = (1 \quad 1 \quad \dots \quad 1) \begin{pmatrix} \gamma_{1,t} \\ \gamma_{2,t} \\ \vdots \\ \gamma_{s,t} \end{pmatrix} + Z_t.$$

Together these equations again constitute a linear state space model. If $V_t = 0$, then this reduces to the deterministic trend model. (Cf. Exercise 10.9.)

A model with both a stochastic linear trend and a stochastic seasonal component is known as a *structural model*. \square

10.9 EXERCISE. Consider the state space model with state equations $\gamma_t = \gamma_{t-1} \cos \lambda + \delta_{t-1} \sin \lambda + V_{t,1}$ and $\delta_t = \gamma_{t-1} \sin \lambda - \delta_{t-1} \cos \lambda + V_{t,2}$ and output equation $Y_t = \gamma_t + W_t$. What does this model reduce to if $V_t \equiv 0$?

10.10 EXERCISE.

- (i) Show that the function (of $t \in \mathbb{Z}$) in (10.3) is periodic with period S .
- (ii) Show that any periodic function $f: \mathbb{Z} \rightarrow \mathbb{R}$ with period S can be written in the form (10.3).

[For (ii) it suffices to show that any vector $(f(1), \dots, f(S))$ can be represented as a linear combination of the vectors $a_s = (\cos \lambda_s, \cos(2\lambda_s), \dots, \cos(S\lambda_s))$ for $s = 0, 1, \dots, \lfloor S/2 \rfloor$ and the vectors $b_s = (\sin \lambda_s, \sin(2\lambda_s), \dots, \sin(S\lambda_s))$, for $s = 1, 2, \dots, \lfloor S/2 \rfloor$. To prove this note that the vectors $e_s = (e^{i\lambda_s}, e^{2i\lambda_s}, \dots, e^{in\lambda_s})^T$ for λ_s running through the natural frequencies is an orthogonal basis of \mathbb{C}^n . The vectors $a_s = \operatorname{Re} e_s$ and $b_s = \operatorname{Im} e_s$ can be seen to be orthogonal, apart from the trivial cases $b_0 = 0$ and $b_{S/2} = 0$ if S is even.]

10.1.1 Notation

The variables X_t and Y_t in a state space model will typically be random vectors. For two random vectors X and Y of dimensions m and n the *covariance* or “cross-covariance” is the $(m \times n)$ matrix $\operatorname{Cov}(X, Y) = E(X - EX)(Y - EY)^T$. The random vectors X and Y are called “uncorrelated” if $\operatorname{Cov}(X, Y) = 0$, or equivalently if $\operatorname{cov}(X_i, Y_j) = 0$ for every pair (i, j) . The *linear span* of a set of vectors is defined as the linear span of all their coordinates. Thus this is a space of (univariate) random variables, rather than random vectors! We shall also understand a projection operator Π , which is a map on the space of random variables, to act coordinatewise on vectors: if X is a vector, then ΠX is the vector consisting of the projections of the coordinates of X . As a vector-valued operator a projection Π is still linear, in that $\Pi(FX + Y) = F\Pi X + \Pi Y$, for any matrix F and random vectors X and Y .

10.2 Kalman Filtering

The *Kalman filter* is a recursive algorithm to compute best linear predictions of the states X_1, X_2, \dots given observations Y_1, Y_2, \dots in the linear state space model (10.2). The core algorithm allows to compute predictions $\Pi_t X_t$ of the states X_t given observed outputs Y_1, \dots, Y_t . Here by “predictions” we mean Hilbert space projections. Given the time values involved, “reconstructions” would perhaps be more appropriate. “Filtering” is the preferred term in systems theory. (In general this term refers to characterizing (the conditional distribution of) a state, or some other quantity at time t , based on observations *until* time t .) Given the reconstructions $\Pi_t X_t$, it is easy to compute predictions of future states and future outputs. “Kalman smoothing”, which is the reconstruction (again through projections) of the full state sequence X_1, \dots, X_n given the outputs Y_1, \dots, Y_n , requires additional steps. (In general “smoothing” refers to characterizing states, or other

quantities, at time t , by observations until time $n > t$. The name appears to result from the fact that reconstructions of a state sequence using observations that include future times tend to have a smoother appearance.)

In the simplest situation the vectors $X_0, V_1, W_1, V_2, W_2, \dots$ are assumed uncorrelated. We shall first derive the filter under the more general assumption that the vectors $X_0, (V_1, W_1), (V_2, W_2), \dots$ are uncorrelated, and in Section 10.2.4 we further relax this condition. The matrices F_t and G_t as well as the covariance matrices of the noise variables (V_t, W_t) are assumed known.

By applying (10.2) recursively, we see that the vector X_t is contained in the linear span of the variables X_0, V_1, \dots, V_t . It is immediate from (10.2) that the vector Y_t is contained in the linear span of X_t and W_t . These facts are true for every $t \in \mathbb{N}$. It follows that under our conditions the noise variables V_t and W_t are uncorrelated with all vectors X_s and Y_s with $s < t$.

Let H_0 be a given closed linear subspace of $L_2(\Omega, \mathcal{U}, P)$ that contains the constants, and for $t \geq 0$ let Π_t be the orthogonal projection onto the space $H_t = H_0 + \text{lin}(Y_1, \dots, Y_t)$. The space H_0 may be viewed as our “knowledge” at time 0; it may be $H_0 = \text{lin}\{1\}$. We assume that the noise vectors V_1, W_1, V_2, \dots are orthogonal to H_0 . Combined with the preceding this shows that the vector (V_t, W_t) is orthogonal to the space H_{t-1} , for every $t \geq 1$.

The Kalman filter consists of the recursions

$$\cdots \rightarrow \begin{pmatrix} \Pi_{t-1}X_{t-1} \\ \text{Cov}(\Pi_{t-1}X_{t-1}) \\ \text{Cov}(X_{t-1}) \end{pmatrix} \xrightarrow{[1]} \begin{pmatrix} \Pi_{t-1}X_t \\ \text{Cov}(\Pi_{t-1}X_t) \\ \text{Cov}(X_t) \end{pmatrix} \xrightarrow{[2]} \begin{pmatrix} \Pi_tX_t \\ \text{Cov}(\Pi_tX_t) \\ \text{Cov}(X_t) \end{pmatrix} \rightarrow \cdots$$

Thus the Kalman filter alternates between “updating the current state”, step [1], and “updating the prediction space”, step [2].

10.11 Theorem (Kalman filter). *The projections Π_tX_t in the linear state space model with uncorrelated vectors $X_0, (V_1, W_1), (V_2, W_2), \dots$ can be recursively computed for $t = 1, 2, \dots$ by alternating the two steps*

$$\begin{aligned} & \Pi_{t-1}X_t = F_t(\Pi_{t-1}X_{t-1}), \\ \text{step [1]} \quad & \text{Cov}(\Pi_{t-1}X_t) = F_t \text{Cov}(\Pi_{t-1}X_{t-1})F_t^T, \\ & \text{Cov}(X_t) = F_t \text{Cov}(X_{t-1})F_t^T + \text{Cov}(V_t). \\ \\ & \Pi_tX_t = \Pi_{t-1}X_t + \Lambda_t\tilde{W}_t, \\ (10.4) \quad \text{step [2]} \quad & \text{Cov}(\Pi_tX_t) = \text{Cov}(\Pi_{t-1}X_t) + \Lambda_t \text{Cov}(\tilde{W}_t)\Lambda_t^T, \end{aligned}$$

where the matrix $\Lambda_t = \text{Cov}(X_t, \tilde{W}_t) \text{Cov}(\tilde{W}_t)^{-1}$ can be computed as in (10.6).

Proof. For step [1] we note that $\Pi_{t-1}V_t = 0$, because $V_t \perp H_0, Y_1, \dots, Y_{t-1}$ by assumption. We next apply Π_t to the state equation $X_t = F_tX_{t-1} + V_t$, and use the linearity of a projection.

Step [2] is based on the vector $\tilde{W}_t = Y_t - \Pi_{t-1}Y_t$. This is called the *innovation* at time t , because it is the part of Y_t that is not explainable at time $t-1$. Because $\Pi_{t-1}W_t = 0$, we have by the measurement equation,

$$(10.5) \quad \tilde{W}_t = Y_t - \Pi_{t-1}Y_t = Y_t - G_t\Pi_{t-1}X_t = G_t(X_t - \Pi_{t-1}X_t) + W_t.$$

The innovation is orthogonal to H_{t-1} , and together with this space spans H_t . It follows that H_t can be orthogonally decomposed as $H_t = H_{t-1} + \text{lin } \tilde{W}_t$ and hence the projection onto H_t is the sum of the projections onto the spaces H_{t-1} and $\text{lin } \tilde{W}_t$. This gives the first equation of step [2], where the finite-dimensional projection on $\text{lin } \tilde{W}_t$ is indeed given by the multiplication with the matrix Λ_t as given. The second equation is an immediate consequence of the first and the orthogonality. It remains to derive equation (10.6) for Λ_t .

Because $W_t \perp X_{t-1}$ the state equation yields $\text{Cov}(X_t, W_t) = \text{Cov}(V_t, W_t)$. By the orthogonality property of projections $\text{Cov}(X_t, X_t - \Pi_{t-1}X_t) = \text{Cov}(X_t - \Pi_{t-1}X_t, X_t)$. Combining this and the identity $\tilde{W}_t = G_t(X_t - \Pi_{t-1}X_t) + W_t$ from (10.5), we compute

$$(10.6) \quad \begin{aligned} \text{Cov}(X_t, \tilde{W}_t) &= \text{Cov}(X_t - \Pi_{t-1}X_t)G_t^T + \text{Cov}(V_t, W_t), \\ \text{Cov}(\tilde{W}_t) &= G_t \text{Cov}(X_t - \Pi_{t-1}X_t)G_t^T + G_t \text{Cov}(V_t, W_t) \\ &\quad + \text{Cov}(W_t, V_t)G_t^T + \text{Cov}(W_t), \\ \text{Cov}(X_t - \Pi_{t-1}X_t) &= \text{Cov}(X_t) - \text{Cov}(\Pi_{t-1}X_t). \end{aligned}$$

The matrix $\text{Cov}(X_t - \Pi_{t-1}X_t)$ is the *prediction error matrix* at time $t-1$ and the last equation follows by Pythagoras' rule. ■

The Kalman algorithm must be initialized in one of its two steps, for instance by providing Π_0X_1 and its covariance matrix, so that the recursion can start with a step of type [2]. It is here where the choice of H_0 plays a role. Choosing $H_0 = \text{lin}(1)$ gives predictions using Y_1, \dots, Y_t as well as an intercept and requires that we know $\Pi_0X_1 = EX_1$. It may also be desired that $\Pi_{t-1}X_t$ is the projection onto $\text{lin}(1, Y_{t-1}, Y_{t-2}, \dots)$ for a stationary extension of Y_t into the past. Then we set Π_0X_1 equal to the projection of X_1 onto $H_0 = \text{lin}(1, Y_0, Y_{-1}, \dots)$.

10.2.1 Future States and Outputs

Predictions of future values of the state variable follow easily from Π_tX_t , because $\Pi_tX_{t+h} = F_{t+h}\Pi_tX_{t+h-1}$ for any $h \geq 1$. Given the predicted states, future outputs can be predicted from the measurement equation by $\Pi_tY_{t+h} = G_{t+h}\Pi_tX_{t+h}$.

* 10.2.2 Missing Observations

A considerable attraction of the Kalman filter algorithm is the ease by which missing observations can be accommodated. This can be achieved by simply filling in the missing data points by “external” variables that are independent of the system. Suppose that (X_t, Y_t) follows the linear state space model (10.2) and that we observe a subset $(Y_t)_{t \in T}$

of the variables Y_1, \dots, Y_n . We define a new set of matrices G_t^* and noise variables W_t^* by

$$\begin{aligned} G_t^* &= G_t, & W_t^* &= W_t, & t &\in T, \\ G_t^* &= 0, & W_t^* &= \bar{W}_t, & t &\notin T, \end{aligned}$$

for random vectors \bar{W}_t that are independent of the vectors that are already in the system. The choice $\bar{W}_t = 0$ is permitted. Next we set

$$\begin{aligned} X_t &= F_t X_{t-1} + V_t, \\ Y_t^* &= G_t^* X_t + W_t^*. \end{aligned}$$

The variables (X_t, Y_t^*) follow a state space model with the same state vectors X_t . For $t \in T$ the outputs $Y_t^* = Y_t$ are identical to the outputs in the original system, while for $t \notin T$ the output is $Y_t^* = \bar{W}_t$, which is pure noise by assumption. Because the noise variables \bar{W}_t cannot contribute to the prediction of the hidden states X_t , best predictions of states based on the observed outputs $(Y_t)_{t \in T}$ or based on Y_1^*, \dots, Y_n^* are identical. We can compute the best predictions based on Y_1^*, \dots, Y_n^* by the Kalman recursions, but with the matrices G_t^* and $\text{Cov}(W_t^*)$ substituted for G_t and $\text{Cov}(W_t)$. Because the Y_t^* with $t \notin T$ will not appear in the projection formula, we can just as well set their “observed values” equal to zero in the computations.

* 10.2.3 Kalman Smoothing

Besides in predicting future states or outputs we may be interested in reconstructing the complete state sequence X_0, X_1, \dots, X_n from the outputs Y_1, \dots, Y_n . The computation of $\Pi_n X_n$ is known as the *filtering problem*, and is computed in step [2] of our description of the Kalman filter. The computation of $\Pi_n X_t$ for $t = 0, 1, \dots, n-1$ is known as the *smoothing problem*. For a given t it can be achieved through the recursions, with \tilde{W}_n as given in (10.5),

$$\begin{pmatrix} \Pi_n X_t \\ \text{Cov}(X_t, \tilde{W}_n) \\ \text{Cov}(X_t, X_n - \Pi_n X_n) \end{pmatrix} \rightarrow \begin{pmatrix} \Pi_{n+1} X_t \\ \text{Cov}(X_t, \tilde{W}_{n+1}) \\ \text{Cov}(X_t, X_{n+1} - \Pi_n X_{n+1}) \end{pmatrix}, \quad n = t, t+1, \dots$$

The initial value at $n = t$ of the recursions and the covariance matrices $\text{Cov}(\tilde{W}_n)$ of the innovations \tilde{W}_n are given by (10.6), and hence can be assumed known.

Because H_{n+1} is the sum of the orthogonal spaces H_n and $\text{lin } \tilde{W}_{n+1}$, we have, as in (10.4),

$$\Pi_{n+1} X_t = \Pi_n X_t + \Lambda_{t,n+1} \tilde{W}_{n+1}, \quad \Lambda_{t,n+1} = \text{Cov}(X_t, \tilde{W}_{n+1}) \text{Cov}(\tilde{W}_{n+1})^{-1}.$$

The recursion for the first coordinate $\Pi_n X_t$ follows from this and the recursions for the second and third coordinates, the covariance matrices $\text{Cov}(X_t, \tilde{W}_{n+1})$ and $\text{Cov}(X_t, X_{n+1} - \Pi_n X_{n+1})$.

Using in turn the state equation and equation (10.4), we find

$$\begin{aligned} \text{Cov}(X_t, X_{n+1} - \Pi_n X_{n+1}) &= \text{Cov}(X_t, F_{n+1}(X_n - \Pi_n X_n) + V_{n+1}) \\ &= \text{Cov}(X_t, F_{n+1}(X_n - \Pi_{n-1} X_n + \Lambda_n \tilde{W}_n)). \end{aligned}$$

This readily gives the recursion for the third component, the matrix Λ_n being known from (10.4)–(10.6). Next using equation (10.5), we find

$$\text{Cov}(X_t, \tilde{W}_{n+1}) = \text{Cov}(X_t, X_{n+1} - \Pi_n X_{n+1}) G_{n+1}^T.$$

* 10.2.4 Lagged Correlations

In the preceding we have assumed that the vectors $X_0, (V_1, W_1), (V_2, W_2), \dots$ are uncorrelated. An alternative assumption is that the vectors $X_0, V_1, (W_1, V_2), (W_2, V_3), \dots$ are uncorrelated. (The awkward pairing of W_t and V_{t+1} can be avoided by writing the state equation as $X_t = F_t X_{t-1} + V_{t-1}$ and next making the assumption as before.) Under this condition the Kalman filter takes a slightly different form, where for economy of computation it can be useful to combine the steps [1] and [2].

Both possibilities are covered by the assumptions that

- the vectors X_0, V_1, V_2, \dots are orthogonal.
- the vectors W_1, W_2, \dots are orthogonal.
- the vectors V_s and W_t are orthogonal for all (s, t) except possibly $s = t$ or $s = t + 1$.
- all vectors are orthogonal to H_0 .

Under these assumptions step [2] of the Kalman filter remains valid as described. Step [1] must be adapted, because it is no longer true that $\Pi_{t-1} V_t = 0$.

Because $V_t \perp H_{t-2}$, we can compute $\Pi_{t-1} V_t$ from the innovation decomposition $H_{t-1} = H_{t-2} + \text{lin } \tilde{W}_{t-1}$, as $\Pi_{t-1} V_t = K_{t-1} \tilde{W}_{t-1}$ for the matrix

$$K_{t-1} = \text{Cov}(V_t, W_{t-1}) \text{Cov}(\tilde{W}_{t-1})^{-1}.$$

Note here that $\text{Cov}(V_t, \tilde{W}_{t-1}) = \text{Cov}(V_t, W_{t-1})$, in view of (10.5). We replace the calculations for step [1] by

$$\begin{aligned} \Pi_{t-1} X_t &= F_t (\Pi_{t-1} X_{t-1}) + K_t \tilde{W}_{t-1}, \\ \text{Cov}(\Pi_{t-1} X_t) &= F_t \text{Cov}(\Pi_{t-1} X_{t-1}) F_t^T + K_t \text{Cov}(\tilde{W}_{t-1}) K_t^T, \\ \text{Cov}(X_t) &= F_t \text{Cov}(X_{t-1}) F_t^T + \text{Cov}(V_t). \end{aligned}$$

This gives a complete description of step [1] of the algorithm, under the assumption that the vector \tilde{W}_{t-1} , and its covariance matrix are kept in memory after the preceding step [2].

The smoothing algorithm goes through as stated except for the recursion for the matrices $\text{Cov}(X_t, X_n - \Pi_n X_n)$. Because $\Pi_n V_{n+1}$ may be nonzero, this becomes

$$\begin{aligned} \text{Cov}(X_t, X_{n+1} - \Pi_n X_{n+1}) &= \text{Cov}(X_t, X_n - \Pi_{n-1} X_n) F_{n+1}^T + \text{Cov}(X_t, \tilde{W}_n) \Lambda_n^T F_{n+1}^T \\ &\quad + \text{Cov}(X_t, \tilde{W}_n) K_n^T. \end{aligned}$$

* 10.3 Nonlinear Filtering

The simplicity of the Kalman filter results from the combined linearity of the state space model and the predictions. These lead to update formulas expressed in the terms of matrix algebra. The principle of recursive predictions can be applied more generally to compute nonlinear predictions in nonlinear state space models, provided the conditional densities of the variables in the system are available and certain integrals involving these densities can be evaluated, analytically, numerically, or by stochastic simulation.

Abusing notation we write a conditional density of a variable X given another variable Y as $p(x|y)$, and a marginal density of X as $p(x)$. Consider the nonlinear state space model (10.1), where we assume that the vectors $X_0, V_1, W_1, V_2, \dots$ are independent. Then the outputs Y_1, \dots, Y_n are conditionally independent given the state sequence X_0, X_1, \dots, X_n , and the conditional law of a single output Y_t given the state sequence depends on X_t only. In principle the (conditional) densities $p(x_0), p(x_1|x_0), p(x_2|x_1), \dots$ and the conditional densities $p(y_t|x_t)$ of the outputs are available from the form of the functions f_t and g_t and the distributions of the noise variables (V_t, W_t) . The joint density of states up till time $n+1$ and outputs up till time n in this hidden Markov model can be expressed in these densities as

$$(10.7) \quad p(x_0)p(x_1|x_0) \cdots p(x_{n+1}|x_n)p(y_1|x_1)p(y_2|x_2) \cdots p(y_n|x_n).$$

The marginal density of the outputs (Y_1, \dots, Y_n) is obtained by integrating this function relative to (x_0, \dots, x_{n+1}) . The conditional density of the state sequence (X_0, \dots, X_{n+1}) given the outputs is proportional to the function in the display, the norming constant being the marginal density of the outputs. In principle, this allows the computation of all conditional expectations $E(X_t|Y_1, \dots, Y_n)$, the (nonlinear) “predictions” of the state. However, because this approach expresses these predictions as a quotient of $n+1$ -dimensional integrals, and n may be large, this is unattractive unless the integrals can be evaluated easily.

An alternative for finding predictions is a recursive scheme for calculating conditional densities, of the form

$$\cdots \rightarrow p(x_{t-1}|y_{t-1}, \dots, y_1) \xrightarrow{[1]} p(x_t|y_{t-1}, \dots, y_1) \xrightarrow{[2]} p(x_t|y_t, \dots, y_1) \rightarrow \cdots$$

This is completely analogous to the updates of the linear Kalman filter: the recursions alternate between “updating the state”, [1], and “updating the prediction space”, [2].

Step [1] can be summarized by the formula, for μ_t the dominating measures,

$$\begin{aligned} p(x_t|y_{t-1}, \dots, y_1) &= \int p(x_t|x_{t-1}, y_{t-1}, \dots, y_1)p(x_{t-1}|y_{t-1}, \dots, y_1) d\mu_{t-1}(x_{t-1}) \\ &= \int p(x_t|x_{t-1})p(x_{t-1}|y_{t-1}, \dots, y_1) d\mu_{t-1}(x_{t-1}). \end{aligned}$$

The second equality follows from the conditional independence of the vectors X_t and Y_{t-1}, \dots, Y_1 given X_{t-1} . This is a consequence of the form of $X_t = f_t(X_{t-1}, V_t)$ and the independence of V_t and the vectors $X_{t-1}, Y_{t-1}, \dots, Y_1$ (which are functions of $X_0, V_1, \dots, V_{t-1}, W_1, \dots, W_{t-1}$).

To obtain a recursion for step [2] we apply Bayes formula to the conditional density of the pair (X_t, Y_t) given Y_{t-1}, \dots, Y_1 to obtain

$$\begin{aligned} p(x_t | y_t, \dots, y_1) &= \frac{p(y_t | x_t, y_{t-1}, \dots, y_1) p(x_t | y_{t-1}, \dots, y_1)}{\int p(y_t | x_t, y_{t-1}, \dots, y_1) p(x_t | y_{t-1}, \dots, y_1) d\mu_t(x_t)} \\ &= \frac{p(y_t | x_t) p(x_t | y_{t-1}, \dots, y_1)}{p(y_t | y_{t-1}, \dots, y_1)}. \end{aligned}$$

The second equation is a consequence of the fact that $Y_t = g_t(X_t, W_t)$ is conditionally independent of Y_{t-1}, \dots, Y_1 given X_t . The conditional density $p(y_t | y_{t-1}, \dots, y_1)$ in the denominator is a nuisance, because it will rarely be available explicitly, but acts only as a norming constant.

The preceding formulas are useful only if the integrals can be evaluated. If analytical evaluation is impossible, then perhaps numerical methods or stochastic simulation could be of help.

If stochastic simulation is the method of choice, then it may be attractive to apply *Markov Chain Monte Carlo* for direct evaluation of the joint law, without recursions. The idea is to simulate a sample from the conditional density $(x_0, \dots, x_{n+1}) \mapsto p(x_0, \dots, x_{n+1} | y_1, \dots, y_n)$ of the states given the outputs. The biggest challenge is the dimensionality of this conditional density. The *Gibbs sampler* overcomes this by simulating recursively from the marginal conditional densities $p(x_t | x_{-t}, y_1, \dots, y_n)$ of the single variables X_t given the outputs Y_1, \dots, Y_n and the vectors $X_{-t} = (X_0, \dots, X_{t-1}, X_{t+1}, \dots, X_{n+1})$ of remaining states. These iterations yield a Markov chain, with the target density $(x_0, \dots, x_{n+1}) \mapsto p(x_0, \dots, x_{n+1} | y_1, \dots, y_n)$ as a stationary density, and under some conditions the iterates of the chain can eventually be thought of as a (dependent) sample from (approximately) this target density. We refer to the literature for general discussion of the Gibbs sampler, but shall show that these marginal distributions are relatively easy to obtain for the general state space model (10.1).

Under independence of the vectors $X_0, V_1, W_1, V_2, \dots$ the joint density of states and outputs takes the hidden Markov form (10.7). The conditional density of X_t given the other vectors is proportional to this expression viewed as function of x_t only. Only three terms of the product depend on x_t and hence we find

$$p(x_t | x_{-t}, y_1, \dots, y_n) \propto p(x_t | x_{t-1}) p(x_{t+1} | x_t) p(y_t | x_t).$$

The norming constant is a function of the conditioning variables x_{-t}, y_1, \dots, y_n only and can be recovered from the fact that the left side is a probability density as a function of x_t . A closer look will reveal that it is equal to $p(y_t | x_{t-1}, x_{t+1}) p(x_{t+1} | x_{t-1})$. However, many simulation methods, in particular the popular Metropolis-Hastings algorithm, can be implemented without an explicit expression for the proportionality constant. The forms of the three densities on the right side should follow from the specification of the system.

The assumption that the variables $X_0, V_1, W_2, V_2, \dots$ are independent may be too restrictive, although it is natural to try and construct the state variables so that it is satisfied. Somewhat more complicated formulas can be obtained under more general

assumptions. Assumptions that are in the spirit of the preceding derivations in this chapter are:

- (i) the vectors X_0, X_1, X_2, \dots form a Markov chain.
- (ii) the vectors Y_1, \dots, Y_n are conditionally independent given X_0, X_1, \dots, X_{n+1} .
- (iii) for each $t \in \{1, \dots, n\}$ the vector Y_t is conditionally independent of the vector $(X_0, \dots, X_{t-2}, X_{t+2}, \dots, X_{n+1})$ given (X_{t-1}, X_t, X_{t+1}) .

The first assumption is true if the vectors X_0, V_1, V_2, \dots are independent. The second and third assumptions are certainly satisfied if all noise vectors $X_0, V_1, W_1, V_2, W_2, V_3, \dots$ are independent. The exercises below give more general sufficient conditions for (i)–(iii) in terms of the noise variables.

In comparison to the hidden Markov situation considered previously not much changes. The joint density of states and outputs can be written in a product form similar to (10.7), the difference being that each conditional density $p(y_t | x_t)$ must be replaced by $p(y_t | x_{t-1}, x_t, x_{t+1})$. The variable x_t then occurs in five terms of the product and hence we obtain

$$\begin{aligned} p(x_t | x_{-t}, y_1, \dots, y_n) &\asymp p(x_{t+1} | x_t) p(x_t | x_{t-1}) \times \\ &\times p(y_{t-1} | x_{t-2}, x_{t-1}, x_t) p(y_t | x_{t-1}, x_t, x_{t+1}) p(y_{t+1} | x_t, x_{t+1}, x_{t+2}). \end{aligned}$$

This formula is general enough to cover the case of the ARV model discussed in the next section.

10.12 EXERCISE. Suppose that $X_0, V_1, W_1, V_2, W_2, V_3, \dots$ are independent, and define states X_t and outputs Y_t by (10.1). Show that (i)–(iii) hold, where in (iii) the vector Y_t is even conditionally independent of $(X_s : s \neq t)$ given X_t .

10.13 EXERCISE. Suppose that $X_0, V_1, V_2, \dots, Z_1, Z_2, \dots$ are independent, and define states X_t and outputs Y_t through (10.2) with $W_t = h_t(V_t, V_{t+1}, Z_t)$ for measurable functions h_t . Show that (i)–(iii) hold. [Under (10.2) there exists a measurable bijection between the vectors (X_0, V_1, \dots, V_t) and (X_0, X_1, \dots, X_n) , and also between the vectors (X_t, X_{t-1}, X_{t+1}) and (X_t, V_t, V_{t+1}) . Thus conditioning on $(X_0, X_1, \dots, X_{n+1})$ is the same as conditioning on $(X_0, V_1, \dots, V_{n+1})$ or on $(X_0, V_1, \dots, V_n, X_{t-1}, X_t, X_{t+1})$.]

* **10.14 EXERCISE.** Show that the condition in the preceding exercise that $W_t = h_t(V_t, V_{t+1}, Z_t)$ for Z_t independent of the other variables is equivalent to the conditional independence of W_t and $X_0, V_1, \dots, V_n, W_s : s \neq t$ given V_t, V_{t+1} .

10.4 Stochastic Volatility Models

The term “volatility”, which we have used at multiple occasions to describe the “movability” of a time series, appears to have its origins in the theory of option pricing. The

Black-Scholes model for pricing an option on a given asset with price S_t is based on a diffusion equation of the type

$$dS_t = \mu_t S_t dt + \sigma_t S_t dB_t.$$

Here B_t is a Brownian motion process and μ_t and σ_t are stochastic processes, which are usually assumed to be adapted to the filtration generated by the process S_t . In the original Black-Scholes model the process σ_t is assumed constant, and the constant is known as the “volatility” of the process S_t .

The Black-Scholes diffusion equation can also be written in the form

$$\log \frac{S_t}{S_0} = \int_0^t (\mu_s - \frac{1}{2}\sigma_s^2) ds + \int_0^t \sigma_s dB_s.$$

If μ and σ are deterministic processes this shows that the log returns $\log S_t/S_{t-1}$ over the intervals $(t-1, t]$ are independent, normally distributed variables ($t = 1, 2, \dots$) with means $\int_{t-1}^t (\mu_s - \frac{1}{2}\sigma_s^2) ds$ and variances $\int_{t-1}^t \sigma_s^2 ds$. In other words, if these means and variances are denoted by $\bar{\mu}_t$ and $\bar{\sigma}_t^2$, then the variables

$$Z_t = \frac{\log S_t/S_{t-1} - \bar{\mu}_t}{\bar{\sigma}_t}$$

are an i.i.d. sample from the standard normal distribution. The standard deviation $\bar{\sigma}_t$ can be viewed as an “average volatility” over the interval $(t-1, t]$. If the processes μ_t and σ_t are not deterministic, then the process Z_t is not necessarily Gaussian. However, if the unit of time is small, so that the intervals $(t-1, t]$ correspond to short time intervals in real time, then it is still believable that the variables Z_t are approximately normally distributed. In that case it is also believable that the processes μ_t and σ_t are approximately constant and hence these processes can replace the averages $\bar{\mu}_t$ and $\bar{\sigma}_t$. Usually, one even assumes that the process $\bar{\mu}_t$ is constant in time. For simplicity of notation we shall take $\bar{\mu}_t$ to be zero in the following, leading to a model of the form

$$\log S_t/S_{t-1} = \sigma_t Z_t,$$

for standard normal variables Z_t and a “volatility” process σ_t . The choice $\bar{\mu}_t = \mu_t - \frac{1}{2}\sigma_t^2 = 0$ corresponds to modelling under the “risk-free” martingale measure, but is made here only for convenience.

There is ample empirical evidence that models with constant volatility do not fit observed financial time series. In particular, this has been documented through a comparison of the option prices predicted by the Black-Scholes formula to the observed prices on the option market. Because the Black-Scholes price of an option on a given asset depends only on the volatility parameter of the asset price process, a single parameter volatility model would allow to calculate this parameter from the observed price of an option on this asset, by inversion of the Black-Scholes formula. Given a range of options written on a given asset, but with different maturities and/or different strike prices, this inversion process usually leads to a range of “implied volatilities”, all connected to the same asset price process. These *implied volatilities* usually vary with the maturity and strike price.

This discrepancy could be taken as proof of the failure of the reasoning behind the Black-Scholes formula, but the more common explanation is that “volatility” is a random process itself. One possible model for this process is a diffusion equation of the type

$$d\sigma_t = \lambda_t \sigma_t dt + \gamma_t \sigma_t dW_t,$$

where W_t is another Brownian motion process. This leads to a “stochastic volatility model in continuous time”. Many different parametric forms for the processes λ_t and γ_t are suggested in the literature. One particular choice is to assume that $\log \sigma_t$ is an *Ornstein-Uhlenbeck process*, i.e. it satisfies

$$d \log \sigma_t = \lambda(\xi - \log \sigma_t) dt + \gamma dW_t.$$

(An application of Itô’s formula show that this corresponds to the choices $\lambda_t = \frac{1}{2}\gamma^2 + \lambda(\xi - \log \sigma_t)$ and $\gamma_t = \gamma$.) The Brownian motions B_t and W_t are often assumed to be dependent, with quadratic variation $\langle B, W \rangle_t = \delta t$ for some parameter $\delta \leq 0$.

A diffusion equation is a stochastic differential equation in continuous time, and does not fit well into our basic set-up, which considers the time variable t to be integer-valued. One approach would be to use continuous time models, but assume that the continuous time processes are observed only at a grid of time points. In view of the importance of the option-pricing paradigm in finance it has been also useful to give a definition of “volatility” directly through discrete time models. These models are usually motivated by an analogy with the continuous time set-up. “Stochastic volatility models” in discrete time are specifically meant to parallel continuous time diffusion models.

The most popular stochastic volatility model in discrete time is the *auto-regressive random variance model* or ARV model. A discrete time analogue of the Ornstein-Uhlenbeck type volatility process σ_t is the specification

$$(10.8) \quad \log \sigma_t = \alpha + \phi \log \sigma_{t-1} + V_{t-1}.$$

For $|\phi| < 1$ and a white noise process V_t this auto-regressive equation possesses a causal stationary solution $\log \sigma_t$. We select this solution in the following. The observed log return process X_t is modelled as

$$(10.9) \quad X_t = \sigma_t Z_t,$$

where it is assumed that the time series (V_t, Z_t) is i.i.d.. The latter implies that Z_t is independent of $V_{t-1}, Z_{t-1}, V_{t-2}, Z_{t-2}, \dots$ and hence of X_{t-1}, X_{t-2}, \dots , but allows dependence between V_t and Z_t . The volatility process σ_t is not observed.

A dependence between V_t and Z_t allows for a leverage effect, one of the “stylized facts” of financial time series. In particular, if V_t and Z_t are negatively correlated, then a small return X_t , which is indicative of a small value of Z_t , suggests a large value of V_t , and hence a large value of the log volatility $\log \sigma_{t+1}$ at the next time instant. (Note that the time index $t - 1$ of V_{t-1} in the auto-regressive equation (10.8) is unusual, because in other situations we would have written V_t . It is meant to support the idea that σ_t is determined at time $t - 1$.)

An ARV stochastic volatility process is a nonlinear state space model. It induces a linear state space model for the log volatilities and log absolute log returns of the form

$$\begin{aligned}\log \sigma_t &= (\alpha \quad \phi) \begin{pmatrix} 1 \\ \log \sigma_{t-1} \end{pmatrix} + V_{t-1} \\ \log |X_t| &= \log \sigma_t + \log |Z_t|.\end{aligned}$$

In order to take the logarithm of the observed series X_t it was necessary to take the absolute value $|X_t|$ first. Usually this is not a serious loss of information, because the sign of X_t is equal to the sign of Z_t , and this is a Bernoulli $\frac{1}{2}$ series if Z_t is symmetrically distributed.

The linear state space form allows the application of the Kalman filter to compute best linear projections of the unobserved log volatilities $\log \sigma_t$ based on the observed log absolute log returns $\log |X_t|$. Although this approach is computationally attractive, a disadvantage is that the best predictions of the volatilities σ_t based on the log returns X_t may be much better than the exponentials of the best linear predictions of the log volatilities $\log \sigma_t$ based on the log returns. Forcing the model in linear form is not entirely natural here. However, the computation of best nonlinear predictions is involved. Markov Chain Monte Carlo methods are perhaps the most promising technique, but are highly computer-intensive.

An ARV process X_t is a martingale difference series relative to its natural filtration $\mathcal{F}_t = \sigma(X_t, X_{t-1}, \dots)$. To see this we first note that by causality $\sigma_t \in \sigma(V_{t-1}, V_{t-2}, \dots)$, whence \mathcal{F}_t is contained in the filtration $\mathcal{G}_t = \sigma(V_s, Z_s: s \leq t)$. The process X_t is actually already a martingale difference relative to this bigger filtration, because by the assumed independence of Z_t from \mathcal{G}_{t-1}

$$E(X_t | \mathcal{G}_{t-1}) = \sigma_t E(Z_t | \mathcal{G}_{t-1}) = 0.$$

A fortiori the process X_t is a martingale difference series relative to the filtration \mathcal{F}_t .

There is no correspondingly simple expression for the conditional variance process $E(X_t^2 | \mathcal{F}_{t-1})$ of an ARV series. By the same argument

$$E(X_t^2 | \mathcal{G}_{t-1}) = \sigma_t^2 E Z_t^2.$$

If $E Z_t^2 = 1$ it follows that $E(X_t^2 | \mathcal{F}_{t-1}) = E(\sigma_t^2 | \mathcal{F}_{t-1})$, but this is intractable for further evaluation. In particular, the process σ_t^2 is not the conditional variance process, unlike in the situation of a GARCH process. Correspondingly, in the present context, in which σ_t is considered the “volatility”, the volatility and conditional variance processes do not coincide.

10.15 EXERCISE. One definition of a volatility process σ_t of a time series X_t is a process σ_t such that X_t/σ_t is an i.i.d. standard normal series. Suppose that $X_t = \tilde{\sigma}_t Z_t$ is a GARCH process with conditional variance process $\tilde{\sigma}_t^2$ and driven by an i.i.d. process Z_t . If Z_t is standard normal, show that $\tilde{\sigma}_t$ qualifies as a volatility process. [Trivial.] If Z_t is a t_p -process show that there exists a process S_t^2 with a chisquare distribution with p degrees of freedom such that $\sqrt{p} \tilde{\sigma}_t / S_t$ qualifies as a volatility process.

10.16 EXERCISE. In the ARV model is σ_t measurable relative to the σ -field generated by X_{t-1}, X_{t-2}, \dots ? Compare with GARCH models.

In view of the analogy with continuous time diffusion processes the assumption that the variables (V_t, Z_t) in (10.8)–(10.9) are normally distributed could be natural. This assumption certainly helps to compute moments of the series. The stationary solution $\log \sigma_t$ of the auto-regressive equation (10.8) is given by (for $|\phi| < 1$)

$$\log \sigma_t = \sum_{j=0}^{\infty} \phi^j (V_{t-1-j} + \alpha) = \sum_{j=0}^{\infty} \phi^j V_{t-1-j} + \frac{\alpha}{1-\phi}.$$

If the time series V_t is i.i.d. Gaussian with mean zero and variance σ^2 , then it follows that the variable $\log \sigma_t$ is normally distributed with mean $\alpha/(1-\phi)$ and variance $\sigma^2/(1-\phi^2)$. The Laplace transform $E \exp(aZ)$ of a standard normal variable Z is given by $\exp(\frac{1}{2}a^2)$. Therefore, under the normality assumption on the process V_t it is straightforward to compute that, for $p > 0$,

$$E|X_t|^p = E e^{p \log \sigma_t} E|Z_t|^p = \exp\left(\frac{1}{2} \frac{\sigma^2 p^2}{1-\phi^2} + \frac{\alpha p}{1-\phi}\right) E|Z_t|^p.$$

Consequently, the kurtosis of the variables X_t can be computed to be

$$\kappa_4(X) = e^{4\sigma^2/(1-\phi^2)} \kappa_4(Z).$$

It follows that the time series X_t possesses a larger kurtosis than the series Z_t . This is true even for $\phi = 0$, but the effect is more pronounced for values of ϕ that are close to 1, which are commonly found in practice. Thus the ARV model is able to explain leptokurtic tails of an observed time series.

Under the assumption that the variables (V_t, Z_t) are i.i.d. and bivariate normally distributed, it is also possible to compute the auto-correlation function of the squared series X_t^2 explicitly. If $\delta = \rho(V_t, Z_t)$ is the correlation between the variables V_t and Z_t , then the vectors $(\log \sigma_t, \log \sigma_{t+h}, Z_t)$ possess a three-dimensional normal distribution with covariance matrix

$$\begin{pmatrix} \beta^2 & \beta^2 \phi^h & 0 \\ \beta^2 \phi^h & \beta^2 & \phi^{h-1} \delta \sigma \\ 0 & \phi^{h-1} \delta \sigma & 1 \end{pmatrix}, \quad \beta^2 = \frac{\sigma^2}{1-\phi^2}.$$

Some calculations show that the auto-correlation function of the square process is given by

$$\rho_{X^2}(h) = \frac{(1 + 4\delta^2 \sigma^2 \phi^{2h-2}) e^{4\sigma^2 \phi^h / (1-\phi^2)} - 1}{3e^{4\sigma^2 / (1-\phi^2)} - 1}, \quad h > 0.$$

The auto-correlation is positive at positive lags and decreases exponentially fast to zero, with a rate depending on the proximity of ϕ to 1. For values of ϕ close to 1, the decrease is relatively slow.

10.17 EXERCISE. Derive the formula for the auto-correlation function.

10.18 EXERCISE. Suppose that the variables V_t and Z_t are independent for every t , in addition to independence of the vectors (V_t, Z_t) , and assume that the variables V_t (but not necessarily the variables Z_t) are normally distributed. Show that

$$\rho_{X^2}(h) = \frac{e^{4\sigma^2\phi^h/(1-\phi^2)} - 1}{\kappa_4(Z)e^{4\sigma^2/(1-\phi^2)} - 1}, \quad h > 0.$$

[Factorize $E\sigma_{t+h}^2\sigma_t^2Z_{t+h}^2Z_t^2$ as $E\sigma_{t+h}^2\sigma_t^2EZ_{t+h}^2Z_t^2$.]

The choice of the logarithmic function in the auto-regressive equation (10.8) has some arbitrariness, and other possibilities, such as a power function, have been explored.

11

Moment and Least Squares Estimators

Suppose that we observe realizations X_1, \dots, X_n from a time series X_t whose distribution is (partly) described by a parameter $\theta \in \mathbb{R}^d$. For instance, an ARMA process with the parameter $(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q, \sigma^2)$, or a GARCH process with parameter $(\alpha, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$, both ranging over a subset of \mathbb{R}^{p+q+1} . In this chapter we discuss two methods of estimation of the parameters, based on the observations X_1, \dots, X_n : the “method of moments” and the “least squares method”.

When applied in the standard form to auto-regressive processes the two methods are essentially the same, but for other models the two methods may yield quite different estimators. Depending on the moments used and the underlying model, least squares estimators can be more efficient, although sometimes they are not usable at all. The “generalized method of moments” tries to bridge the efficiency gap, by increasing the number of moments employed.

Moment and least squares estimators are popular in time series analysis, but in general they are less accurate than maximum likelihood and Bayes estimators. The difference in efficiency depends on the model and the true distribution of the time series. Maximum likelihood estimation using a Gaussian model can be viewed as an extension of the method of least squares. We discuss the method of maximum likelihood in Chapter 13.

11.1 Yule-Walker Estimators

Suppose that the time series $X_t - \mu$ is a stationary auto-regressive process of known order p and with unknown parameters ϕ_1, \dots, ϕ_p and σ^2 . The mean $\mu = \mathbb{E}X_t$ of the series may also be unknown, but we assume that it is estimated by \bar{X}_n and concentrate attention on estimating the remaining parameters.

From Chapter 8 we know that the parameters of an auto-regressive process are not uniquely determined by the series X_t , but can be replaced by others if the white noise process is changed appropriately as well. We shall aim at estimating the parameters

under the assumption that the series is causal. This is equivalent to requiring that all roots of the polynomial $\phi(z) = 1 - \phi_1 z - \cdots - \phi_p z^p$ are outside the unit circle.

Under causality the best linear predictor of X_{p+1} based on $1, X_p, \dots, X_1$ is given by $\Pi_p X_{p+1} = \mu + \phi_1(X_p - \mu) + \cdots + \phi_p(X_1 - \mu)$. (See Section 8.4.) Alternatively, the best linear predictor can be obtained by solving the general prediction equations (2.4). Combined this shows that the parameters ϕ_1, \dots, ϕ_p satisfy

$$\begin{pmatrix} \gamma_X(0) & \gamma_X(1) & \cdots & \gamma_X(p-1) \\ \gamma_X(1) & \gamma_X(0) & \cdots & \gamma_X(p-2) \\ \vdots & \vdots & & \vdots \\ \gamma_X(p-1) & \gamma_X(p-2) & \cdots & \gamma_X(0) \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_p \end{pmatrix} = \begin{pmatrix} \gamma_X(1) \\ \gamma_X(2) \\ \vdots \\ \gamma_X(p) \end{pmatrix}.$$

We abbreviate this system of equations by $\Gamma_p \vec{\phi}_p = \vec{\gamma}_p$. These equations, known as the *Yule-Walker equations*, express the parameters into second moments of the observations. The *Yule-Walker estimators* are defined by replacing the true auto-covariances $\gamma_X(h)$ by their sample versions $\hat{\gamma}_n(h)$ and next solving for ϕ_1, \dots, ϕ_p . This leads to the estimators

$$\hat{\vec{\phi}}_p := \begin{pmatrix} \hat{\phi}_1 \\ \hat{\phi}_2 \\ \vdots \\ \hat{\phi}_p \end{pmatrix} = \begin{pmatrix} \hat{\gamma}_n(0) & \hat{\gamma}_n(1) & \cdots & \hat{\gamma}_n(p-1) \\ \hat{\gamma}_n(1) & \hat{\gamma}_n(0) & \cdots & \hat{\gamma}_n(p-2) \\ \vdots & \vdots & & \vdots \\ \hat{\gamma}_n(p-1) & \hat{\gamma}_n(p-2) & \cdots & \hat{\gamma}_n(0) \end{pmatrix}^{-1} \begin{pmatrix} \hat{\gamma}_n(1) \\ \hat{\gamma}_n(2) \\ \vdots \\ \hat{\gamma}_n(p) \end{pmatrix} =: \hat{\Gamma}_p^{-1} \hat{\gamma}_p.$$

The parameter σ^2 is by definition the variance of Z_{p+1} , which is the prediction error $X_{p+1} - \Pi_p X_{p+1}$ when predicting X_{p+1} by the preceding observations (under the assumption that the time series is causal). By the orthogonality of the prediction error and the predictor $\Pi_p X_{p+1}$, and Pythagoras' rule,

$$(11.1) \quad \sigma^2 = \text{var } X_{p+1} - \text{var}(\Pi_p X_{p+1}) = \gamma_X(0) - \vec{\phi}_p^T \Gamma_p \vec{\phi}_p.$$

We define an estimator $\hat{\sigma}^2$ by replacing all unknowns by their moment estimators, i.e.

$$\hat{\sigma}^2 = \hat{\gamma}_n(0) - \hat{\vec{\phi}}_p^T \hat{\Gamma}_p \hat{\vec{\phi}}_p.$$

11.1 EXERCISE. An alternative method to derive the Yule-Walker equations is to work out the equations $\text{cov}(\phi(B)(X_t - \mu), X_{t-k} - \mu) = \text{cov}(Z_t, \sum_{j \geq 0} \psi_j Z_{t-j-k})$ for $k = 0, \dots, p$. Check this. Do you need causality? What if the time series would not be causal?

11.2 EXERCISE. Show that the matrix Γ_p is invertible for every p . [Suggestion: write $\alpha^T \Gamma_p \alpha$ in terms of the spectral density.]

Another reasonable method to find estimators is to start from the fact that the true values of ϕ_1, \dots, ϕ_p minimize the expectation

$$(\beta_1, \dots, \beta_p) \mapsto \mathbb{E}(X_t - \mu - \beta_1(X_{t-1} - \mu) - \cdots - \beta_p(X_{t-p} - \mu))^2.$$

The *least squares estimators* are defined by replacing this criterion function by an “empirical” (i.e. observable) version of it and next minimizing this. Let $\hat{\phi}_1, \dots, \hat{\phi}_p$ minimize the function

$$(11.2) \quad (\beta_1, \dots, \beta_p) \mapsto \frac{1}{n} \sum_{t=p+1}^n (X_t - \bar{X}_n - \beta_1(X_{t-1} - \bar{X}_n) - \dots - \beta_p(X_{t-p} - \bar{X}_n))^2.$$

The minimum value itself is a reasonable estimator of the minimum value of the expectation of this criterion function, which is $EZ_t^2 = \sigma^2$. The least squares estimators $\hat{\phi}_j$ obtained in this way are not identical to the Yule-Walker estimators, but the difference is small. We can see this by deriving the least squares estimators as the solution of a system of equations. The right side of (11.2) is n times the square of the norm $\|Y_n - D_n \vec{\beta}_p\|$ for $\vec{\beta}_p = (\beta_1, \dots, \beta_p)^T$ the vector of parameters and Y_n and D_n the vector and matrix given by

$$Y_n = \begin{pmatrix} X_n - \bar{X}_n \\ X_{n-1} - \bar{X}_n \\ \vdots \\ X_{p+1} - \bar{X}_n \end{pmatrix}, \quad D_n = \begin{pmatrix} X_{n-1} - \bar{X}_n & X_{n-2} - \bar{X}_n & \cdots & X_{n-p} - \bar{X}_n \\ X_{n-2} - \bar{X}_n & X_{n-3} - \bar{X}_n & \cdots & X_{n-p-1} - \bar{X}_n \\ \vdots & \vdots & \ddots & \vdots \\ X_p - \bar{X}_n & X_{p-1} - \bar{X}_n & \cdots & X_1 - \bar{X}_n \end{pmatrix}.$$

The norm $\beta \mapsto \|Y_n - D_n \vec{\beta}_p\|$ is minimized by the vector $\vec{\beta}_p$ such that $D_n \vec{\beta}_p$ is the projection of the vector Y_n onto the range of the matrix D_n . By the projection theorem, Theorem 2.11, this is characterized by the relationship that the residual $Y_n - D_n \vec{\beta}_p$ is orthogonal to the range of D_n . Since this range is spanned by the rows of D_n^T , it follows that $D_n^T(Y_n - D_n \vec{\beta}_p) = 0$. This *normal equation* can be solved for $\vec{\beta}_p$ to yield that the minimizing vector is given by

$$\hat{\phi}_p = \left(\frac{1}{n} D_n^T D_n \right)^{-1} \frac{1}{n} D_n^T (\vec{X}_n - \bar{X}_n).$$

At closer inspection this vector is nearly identical to the Yule-Walker estimators. Indeed, for every $s, t \in \{1, \dots, p\}$,

$$\begin{aligned} \left(\frac{1}{n} D_n^T D_n \right)_{s,t} &= \frac{1}{n} \sum_{j=p+1}^n (X_{j-s} - \bar{X}_n)(X_{j-t} - \bar{X}_n) \approx \hat{\gamma}_n(s-t) = (\hat{\Gamma}_p)_{s,t}, \\ \left(\frac{1}{n} D_n^T (\vec{X}_n - \bar{X}_n) \right)_t &= \frac{1}{n} \sum_{j=p+1}^n (X_{j-t} - \bar{X}_n)(X_j - \bar{X}_n) \approx \hat{\gamma}_n(t). \end{aligned}$$

Asymptotically the difference between the Yule-Walker and least squares estimators is negligible. They possess the same (normal) limit distribution.

11.3 Theorem. Let $(X_t - \mu)$ be a causal $AR(p)$ process relative to an i.i.d. sequence Z_t with finite fourth moments. Then both the Yule-Walker and the least squares estimators satisfy, with Γ_p the covariance matrix of (X_1, \dots, X_p) ,

$$\sqrt{n}(\hat{\vec{\phi}}_p - \vec{\phi}_p) \rightsquigarrow N(0, \sigma^2 \Gamma_p^{-1}).$$

Proof. We can assume without loss of generality that $\mu = 0$. The AR equations $\phi(B)X_t = Z_t$ for $t = n, n-1, \dots, p+1$ can be written in the matrix form

$$\begin{pmatrix} X_n \\ X_{n-1} \\ \vdots \\ X_{p+1} \end{pmatrix} = \begin{pmatrix} X_{n-1} & X_{n-2} & \cdots & X_{n-p} \\ X_{n-2} & X_{n-3} & \cdots & X_{n-p-1} \\ \vdots & \vdots & & \vdots \\ X_p & X_{p-1} & \cdots & X_1 \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_p \end{pmatrix} + \begin{pmatrix} Z_n \\ Z_{n-1} \\ \vdots \\ Z_{p+1} \end{pmatrix} = D_n \vec{\phi}_p + \vec{Z}_n,$$

for \vec{Z}_n the vector with coordinates $Z_t + \bar{X}_n \sum \phi_i$, and D_n the “design matrix” as before. We can solve $\vec{\phi}_p$ from this as, writing \vec{X}_n for the vector on the left,

$$\vec{\phi}_p = (D_n^T D_n)^{-1} D_n^T (\vec{X}_n - \vec{Z}_n).$$

Combining this with the analogous representation of the least squares estimators $\hat{\phi}_j$ we find

$$\sqrt{n}(\hat{\vec{\phi}}_p - \vec{\phi}_p) = \left(\frac{1}{n} D_n^T D_n \right)^{-1} \frac{1}{\sqrt{n}} D_n^T (\vec{Z}_n - \bar{X}_n (1 - \sum_i \phi_i) \vec{1}).$$

Because X_t is an auto-regressive process, it possesses a representation $X_t = \sum_j \psi_j Z_{t-j}$ for a sequence ψ_j with $\sum_j |\psi_j| < \infty$. Therefore, the results of Chapter 5 apply and show that $n^{-1} D_n^T D_n \xrightarrow{P} \Gamma_p$. (In view of Problem 11.2 this also shows that the matrix $D_n^T D_n$ is invertible, as was assumed implicitly in the preceding.)

In view of Slutsky’s lemma it now suffices to show that

$$\frac{1}{\sqrt{n}} D_n^T \vec{Z}_n \rightsquigarrow N(0, \sigma^2 \Gamma_p), \quad \frac{1}{\sqrt{n}} D_n^T 1 \bar{X}_n \xrightarrow{P} 0.$$

A typical coordinate of the last vector is (for $h = 1, \dots, p$)

$$\frac{1}{\sqrt{n}} \sum_{t=p+1}^n (X_{t-h} - \bar{X}_n) \bar{X}_n = \frac{1}{\sqrt{n}} \sum_{t=p+1}^n X_{t-h} \bar{X}_n - \frac{n-p}{\sqrt{n}} \bar{X}_n^2.$$

In view of Theorem 4.5 and the assumption that $\mu = 0$, the sequence $\sqrt{n} \bar{X}_n$ converges in distribution. Hence both terms on the right side are of the order $O_P(1/\sqrt{n})$.

A typical coordinate of the first vector is (for $h = 1, \dots, p$)

$$\frac{1}{\sqrt{n}} \sum_{t=p+1}^n (X_{t-h} - \bar{X}_n) Z_t = \frac{1}{\sqrt{n}} \sum_{t=1}^{n-p} Y_t + O_P\left(\frac{1}{\sqrt{n}}\right),$$

for $Y_t = X_{p+t-h}Z_{p+t}$. By causality of the series X_t we have $Z_{p+t} \perp X_{p+t-s}$ for $s > 0$ and hence $EY_t = EX_{p+t-s}EZ_{p+t} = 0$ for every t . The same type of arguments as in Chapter 5 will give the asymptotic normality of the sequence $\sqrt{n}\bar{Y}_n$, with asymptotic variance

$$\sum_{g=-\infty}^{\infty} \gamma_Y(g) = \sum_{g=-\infty}^{\infty} EX_{p+g-h}Z_{p+g}X_{p-h}Z_p.$$

In this series all terms with $g > 0$ vanish because Z_{p+g} is independent of the vector $(X_{p+g-h}, X_{p-h}, Z_p)$, by the assumption of causality and the fact that Z_t is an i.i.d. sequence. All terms with $g < 0$ vanish by symmetry. Thus the series is equal to $\gamma_Y(0) = EX_{p-h}^2 Z_p^2 = \gamma_X(0)\sigma^2$, which is the diagonal element of $\sigma^2\Gamma_p$. This concludes the proof of the convergence in distribution of all marginals of $n^{-1/2}D_n^T \bar{Z}_n$. The joint convergence is proved in similarly, with the help of the Cramér-Wold device.

This concludes the proof of the asymptotic normality of the least squares estimators. The Yule-Walker estimators can be proved to be asymptotically equivalent to the least squares estimators, in that the difference is of the order $o_P(1/\sqrt{n})$. Next we apply Slutsky's lemma. ■

11.4 EXERCISE. Show that the time series Y_t in the preceding proof is strictly stationary.

* **11.5 EXERCISE.** Give a complete proof of the asymptotic normality of $\sqrt{n}\bar{Y}_n$ as defined in the preceding proof, along the lines sketched, or using the fact $n\bar{Y}_n$ is a martingale.

11.1.1 Order Selection

In the preceding derivation of the properties of the least squares and Yule-Walker estimators the order p of the AR process is assumed known a-priori. Theorem 11.3 is false if $X_t - \mu$ were in reality an AR(p_0) process of order $p_0 > p$. In that case $\hat{\phi}_1, \dots, \hat{\phi}_p$ are estimators of the coefficients of the best linear predictor based on p observations, but need not converge to the p_0 coefficients $\phi_1, \dots, \phi_{p_0}$. On the other hand, Theorem 11.3 remains valid if the series X_t is an auto-regressive process of “true” order p_0 strictly smaller than the order p used to define the estimators. This follows, since for $p_0 \leq p$ an AR(p_0) process is also an AR(p) process, albeit that $\phi_{p_0+1}, \dots, \phi_p$ are zero. In view of the Theorem 11.3, if $\hat{\phi}_1^{(p)}, \dots, \hat{\phi}_j^{(p)}$ are the Yule-Walker estimators when fitting an AR(p) model and the observations are an AR(p_0) process with $p_0 \leq p$, then

$$\sqrt{n}\hat{\phi}_j^{(p)} \rightsquigarrow N(0, \sigma^2(\Gamma_p^{-1})_{j,j}), \quad j = p_0 + 1, \dots, p.$$

Thus “overfitting” (choosing too big an order) does not cause great harm: the estimators of the “unnecessary” coefficients $\phi_{p_0+1}, \dots, \phi_p$ converge to zero at rate $1/\sqrt{n}$. This is reconforting. However, there is also a price to be paid by overfitting. By Theorem 11.3, if fitting an AR(p)-model, then the estimators of the first p_0 coefficients satisfy

$$\sqrt{n} \left(\begin{pmatrix} \hat{\phi}_1^{(p)} \\ \vdots \\ \hat{\phi}_{p_0}^{(p)} \end{pmatrix} - \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_{p_0} \end{pmatrix} \right) \rightsquigarrow N(0, \sigma^2(\Gamma_p^{-1})_{s,t=1,\dots,p_0}).$$

The covariance matrix in the right side, the $(p_0 \times p_0)$ upper principal submatrix of the $(p \times p)$ matrix Γ_p^{-1} , is not equal to $\Gamma_{p_0}^{-1}$, which would be the asymptotic covariance matrix if we fitted an AR model of the “correct” order p_0 . In fact, it is bigger in that

$$(\Gamma_p^{-1})_{s,t=1,\dots,p_0} - \Gamma_{p_0}^{-1} \geq 0.$$

(Here $A \geq 0$ means that the matrix A is nonnegative definite.) In particular, the diagonal elements of these matrices, which are the differences of the asymptotic variances of the estimators $\phi_j^{(p)}$ and the estimators $\phi_j^{(p_0)}$, are nonnegative. Thus overfitting leads to more uncertainty in the estimators of both $\phi_1, \dots, \phi_{p_0}$ and $\phi_{p_0+1}, \dots, \phi_p$. Fitting an autoregressive process of very high order p increases the chance of having the model fit the data, but generally will result in poor estimates of the coefficients, which render the final outcome less useful.

* **11.6 EXERCISE.** Prove the assertion that the given matrix is nonnegative definite.

In practice we do not know the correct order to use. A suitable order is often determined by a preliminary data-analysis, such as an inspection of the plot of the sample partial auto-correlation function. More formal methods are discussed within the general context of maximum likelihood estimation in Chapter 13.

11.7 Example. If we fit an AR(1) process to observations of an AR(1) series, then the asymptotic covariance of $\sqrt{n}(\hat{\phi}_1 - \phi_1)$ is equal to $\sigma^2 \Gamma_1^{-1} = \sigma^2 / \gamma_X(0)$. If to this same process we fit an AR(2) process, then we obtain estimators $(\hat{\phi}_1^{(2)}, \hat{\phi}_2^{(2)})$ (not related to the earlier $\hat{\phi}_1$) such that $\sqrt{n}(\hat{\phi}_1^{(2)} - \phi_1, \hat{\phi}_2^{(2)})$ has asymptotic covariance matrix

$$\sigma^2 \Gamma_2^{-1} = \sigma^2 \begin{pmatrix} \gamma_X(0) & \gamma_X(1) \\ \gamma_X(1) & \gamma_X(0) \end{pmatrix}^{-1} = \frac{\sigma^2}{\gamma_X^2(0) - \gamma_X^2(1)} \begin{pmatrix} \gamma_X(0) & -\gamma_X(1) \\ -\gamma_X(1) & \gamma_X(0) \end{pmatrix}.$$

Thus the asymptotic variance of the sequence $\sqrt{n}(\hat{\phi}_1^{(2)} - \phi_1)$ is equal to

$$\frac{\sigma^2 \gamma_X(0)}{\gamma_X^2(0) - \gamma_X^2(1)} = \frac{\sigma^2}{\gamma_X(0)} \frac{1}{1 - \phi_1^2}.$$

(Note that $\phi_1 = \gamma_X(1)/\gamma_X(0)$.) Thus overfitting by one degree leads to a loss in efficiency of $1 - \phi_1^2$. This is particularly harmful if the true value of $|\phi_1|$ is close to 1, i.e. the time series is close to being a (nonstationary) random walk. \square

11.1.2 Partial Auto-Correlations

Recall that the partial auto-correlation coefficient $\alpha_X(h)$ of a centered time series X_t is the coefficient of X_1 in the formula $\beta_1 X_h + \dots + \beta_h X_1$ for the best linear predictor of X_{h+1} based on X_1, \dots, X_h . In particular, for the causal AR(p) process satisfying $X_t = \phi_1 X_{t-1} + \dots + \phi_p X_{t-p} + Z_t$ we have $\alpha_X(p) = \phi_p$ and $\alpha_X(h) = 0$ for $h > p$. The sample partial auto-correlation coefficient is defined in Section 5.4 as the Yule-Walker estimator $\hat{\phi}_h$ when fitting an AR(h) model. This connection provides an alternative method to derive the limit distribution in the special situation of autoregressive processes. The simplicity of the result makes it worth the effort.

11.8 Corollary. *Let $X_t - \mu$ be a causal stationary $AR(p)$ process relative to an i.i.d. sequence Z_t with finite fourth moments. Then, for every $h > p$,*

$$\sqrt{n} \hat{\alpha}_n(h) \rightsquigarrow N(0, 1).$$

Proof. For $h > p$ the time series $X_t - \mu$ is also an $AR(h)$ process and hence we can apply Theorem 11.3 to find that the Yule-Walker estimators $\hat{\phi}_1^{(h)}, \dots, \hat{\phi}_h^{(h)}$ when fitting an $AR(h)$ model satisfy

$$\sqrt{n}(\hat{\phi}_h^{(h)} - \phi_h^{(h)}) \rightsquigarrow N(0, \sigma^2(\Gamma_h^{-1})_{h,h}).$$

The left side is exactly $\sqrt{n} \hat{\alpha}_n(h)$. We show that the variance of the normal distribution on the right side is unity. By Cramér's rule the (h, h) -element of the matrix Γ_h^{-1} can be found as $\det \Gamma_{h-1} / \det \Gamma_h$. By the prediction equations we have for $h \geq p$

$$\begin{pmatrix} \gamma_X(0) & \gamma_X(1) & \cdots & \gamma_X(h-1) \\ \gamma_X(1) & \gamma_X(0) & \cdots & \gamma_X(h-2) \\ \vdots & \vdots & & \vdots \\ \gamma_X(h-1) & \gamma_X(h-2) & \cdots & \gamma_X(0) \end{pmatrix} \begin{pmatrix} \phi_1 \\ \vdots \\ \phi_p \\ 0 \\ \vdots \\ 0 \end{pmatrix} = \begin{pmatrix} \gamma_X(1) \\ \gamma_X(2) \\ \vdots \\ \gamma_X(h) \end{pmatrix}.$$

This expresses the vector on the right as a linear combination of the first p columns of the matrix Γ_h on the left. We can use this to rewrite $\det \Gamma_{h+1}$ (by a “sweeping” operation) in the form

$$\begin{vmatrix} \gamma_X(0) & \gamma_X(1) & \cdots & \gamma_X(h) \\ \gamma_X(1) & \gamma_X(0) & \cdots & \gamma_X(h-1) \\ \vdots & \vdots & & \vdots \\ \gamma_X(h) & \gamma_X(h-1) & \cdots & \gamma_X(0) \end{vmatrix} = \begin{vmatrix} \gamma_X(0) - \phi_1 \gamma_X(1) - \cdots - \phi_p \gamma_X(p) & 0 & \cdots & 0 \\ & \gamma_X(1) & \cdots & \gamma_X(h-1) \\ & \vdots & & \vdots \\ & \gamma_X(h) & \cdots & \gamma_X(0) \end{vmatrix}.$$

The $(1, 1)$ -element in the last determinant is equal to σ^2 by (11.1). Thus this determinant is equal to $\sigma^2 \det \Gamma_h$ and the theorem follows. ■

This corollary can be used to determine a suitable order p if fitting an auto-regressive model to a given observed time series. The true partial auto-correlation coefficients of lags higher than the true order p are all zero, and we should expect that the sample partial auto-correlation coefficients are inside a band of the type $(-1.96/\sqrt{n}, 1.96/\sqrt{n})$. Thus we should not choose the order equal to p if $\hat{\alpha}_n(p+k)$ is outside this band for too many $k \geq 1$. Here we should expect a fraction of 5 % of the $\hat{\alpha}_n(p+k)$ for which we perform this “test” to be outside the band in any case.

To turn this procedure in a more formal statistical test we must also take the dependence between the different $\hat{\alpha}_n(p+k)$ into account, but this appears to be complicated.

- * **11.9 EXERCISE.** Find the asymptotic limit distribution of the sequence $(\hat{\alpha}_n(h), \hat{\alpha}_n(h+1))$ for $h > p$, e.g. in the case that $p = 0$ and $h = 1$.

* **11.1.3 Indirect Estimation**

The parameters ϕ_1, \dots, ϕ_p of a causal auto-regressive process are exactly the coefficients of the one-step ahead linear predictor using p variables from the past. This makes application of the least squares method to obtain estimators for these parameters particularly straightforward. For an arbitrary stationary time series the best linear predictor of X_{p+1} given $1, X_1, \dots, X_p$ is the linear combination $\mu + \phi_1(X_p - \mu) + \dots + \phi_p(X_1 - \mu)$ whose coefficients satisfy the prediction equations (2.4). The Yule-Walker estimators are the solutions to these equations after replacing the true auto-covariances by the sample auto-covariances. It follows that the Yule-Walker estimators can be considered estimators for the prediction coefficients (using p variables from the past) for any stationary time series. The case of auto-regressive processes is special only in that these prediction coefficients are exactly the parameters of the model.

Furthermore, it remains true that the Yule-Walker estimators are \sqrt{n} -consistent and asymptotically normal. This does not follow from Theorem 11.3, because this uses the auto-regressive structure explicitly, but it can be inferred from the asymptotic normality of the auto-covariances, given in Theorem 5.8. (The argument is the same as used in Section 5.4. The asymptotic covariance matrix will be different from the one in Theorem 11.3, and more complicated.)

If the prediction coefficients (using a fixed number of past variables) are not the parameters of main interest, then these remarks may seem little useful. However, if the parameter of interest θ is of dimension d , then we may hope that there exists a one-to-one relationship between θ and the prediction coefficients ϕ_1, \dots, ϕ_p if we choose $p = d$. (More generally, we can apply this to a subvector of θ and a matching number of ϕ_j 's.) Then we can first estimate ϕ_1, \dots, ϕ_d by the Yule-Walker estimators and next employ the relationship between ϕ_1, \dots, ϕ_p to infer an estimate of θ . If the inverse map giving θ as a function of ϕ_1, \dots, ϕ_d is differentiable, then it follows by the Delta-method that the resulting estimator for θ is \sqrt{n} -consistent and asymptotically normal, and hence we obtain good estimators.

If the relationship between θ and (ϕ_1, \dots, ϕ_d) is complicated, then this idea may be hard to implement. One way out of this problem is to determine the prediction coefficients ϕ_1, \dots, ϕ_d for a grid of values of θ , possibly through simulation. The value on the grid that yields the Yule-Walker estimators is the estimator for θ we are looking for.

- 11.10 EXERCISE.** Indicate how you could obtain (approximate) values for ϕ_1, \dots, ϕ_p given θ using computer simulation, for instance for a stochastic volatility model.

11.2 Moment Estimators

The Yule-Walker estimators can be viewed as arising from a comparison of sample auto-covariances to true auto-covariances and therefore are examples of *moment estimators*. Moment estimators are defined in general by matching sample moments and population moments. *Population moments* of a time series X_t are true expectations of functions of the variables X_t , for instance,

$$E_\theta X_t, \quad E_\theta X_t^2, \quad E_\theta X_{t+h} X_t, \quad E_\theta X_{t+h}^2 X_t^2.$$

In every case, the subscript θ indicates the dependence on the unknown parameter θ : in principle, every of these moments is a function of θ . The principle of the method of moments is to estimate θ by that value $\hat{\theta}_n$ for which the corresponding population moments coincide with a corresponding sample moment, for instance,

$$\frac{1}{n} \sum_{t=1}^n X_t, \quad \frac{1}{n} \sum_{t=1}^n X_t^2, \quad \frac{1}{n} \sum_{t=1}^n X_{t+h} X_t, \quad \frac{1}{n} \sum_{t=1}^n X_{t+h}^2 X_t^2.$$

From Chapter 5 we know that these sample moments converge, as $n \rightarrow \infty$, to the true moments, and hence it is believable that the sequence of moment estimators $\hat{\theta}_n$ also converges to the true parameter, under some conditions.

Rather than true moments it is often convenient to define moment estimators through derived moments such as an auto-covariance at a fixed lag, or an auto-correlation, which are both functions of moments of degree smaller than 2. These derived moments are then matched to the corresponding sample quantities.

The choice of moments to be used is crucial for the existence and consistency of the moment estimators, and also for their efficiency.

For existence we generally need to match as many moments as there are parameters in the model. With fewer moments we should expect a moment estimator to be not uniquely defined, whereas with more moments no solution to the moment equations may exist. Because in general the moments are highly nonlinear functions of the parameters, it is hard to make this statement precise, as it is hard to characterize solutions of systems of nonlinear equations in general. This is illustrated already in the case of moving average processes, where a characterization of the existence of solutions requires effort, and where conditions and restrictions are needed to ensure their uniqueness. (Cf. Section 11.2.3.)

To ensure consistency and improve efficiency it is necessary to use moments that can be estimated well from the data. Auto-covariances at high lags, or moments of high degree should generally be avoided. Besides on the quality of the initial estimates, the efficiency of the moment estimators also depends on the inverse map giving the parameter as a function of the moments. To see this we may formalize the method of moments through the scheme

$$\begin{aligned} \phi(\theta) &= E_\theta f(X_t, \dots, X_{t+h}), \\ \phi(\hat{\theta}_n) &= \frac{1}{n} \sum_{t=1}^n f(X_t, \dots, X_{t+h}). \end{aligned}$$

Here $f: \mathbb{R}^{h+1} \rightarrow \mathbb{R}^d$ is a given map, which defines the moments used. (For definiteness we allow it to depend on the joint distribution of at most $h+1$ consecutive observations.)

We shall assume that the time series $t \mapsto f(X_t, \dots, X_{t+h})$ is strictly stationary, so that the mean values $\phi(\theta)$ in the first line do not depend on t , and for simplicity of notation we assume that we observe X_1, \dots, X_{n+h} , so that the right side of the second line is indeed an observable quantity. If the map $\phi: \Theta \rightarrow \mathbb{R}^d$ is one-to-one, then the second line uniquely defines the estimator $\hat{\theta}_n$ as the inverse

$$\hat{\theta}_n = \phi^{-1}(\hat{f}_n), \quad \hat{f}_n = \frac{1}{n} \sum_{t=1}^n f(X_t, \dots, X_{t+h}).$$

We shall generally construct \hat{f}_n such that it converges in probability to its mean $\phi(\theta)$ as $n \rightarrow \infty$. If this is the case and ϕ^{-1} is continuous at $\phi(\theta)$, then we have that $\hat{\theta}_n \rightarrow \phi^{-1}\phi(\theta) = \theta$, in probability as $n \rightarrow \infty$, and hence the moment estimator is asymptotically consistent.

Many sample moments converge at \sqrt{n} -rate, with a normal limit distribution. This allows to refine the consistency result, in view of the Delta-method, given by Theorem 3.15. If ϕ^{-1} is differentiable at $\phi(\theta)$ with derivative of full rank, and $\sqrt{n}(\hat{f}_n - \phi(\theta))$ converges in distribution to a normal distribution with mean zero and covariance matrix Σ_θ , then

$$\sqrt{n}(\hat{\theta}_n - \theta) \rightsquigarrow N(0, \phi'_\theta{}^{-1} \Sigma_\theta (\phi'_\theta{}^{-1})^T).$$

Here $\phi'_\theta{}^{-1}$ is the derivative of ϕ^{-1} at $\phi(\theta)$, which is the inverse of the derivative of ϕ at θ . Under these conditions, the moment estimators are \sqrt{n} -consistent with a normal limit distribution, a desirable property.

The size of the asymptotic covariance matrix $\phi'_\theta{}^{-1} \Sigma_\theta (\phi'_\theta{}^{-1})^T$ depends both on the accuracy by which the chosen moments can be estimated from the data (through the matrix Σ_θ) and the “smoothness” of the inverse ϕ^{-1} . If the inverse map has a “large” derivative, then extracting the moment estimator $\hat{\theta}_n$ from the sample moments \hat{f}_n magnifies the error of \hat{f}_n as an estimate of $\phi(\theta)$, and the moment estimator will be relatively inefficient. Unfortunately, it is hard to see how a particular implementation of the method of moments works out without doing (part of) the algebra leading to the asymptotic covariance matrix. Furthermore, the outcome may depend on the true value of the parameter, a given moment estimator being relatively efficient for some parameter values, but (very) inefficient for others.

11.2.1 Generalized Moment Estimators

Moment estimators are measurable functions of the sample moments \hat{f}_n and hence cannot be better than the best estimator based on \hat{f}_n . In most cases summarizing the data through the sample moments \hat{f}_n incurs a loss of information. Only if the sample moments are sufficient (in the statistical sense), moment estimators can be fully efficient. Sufficiency is an exceptional situation. The loss of information can be diminished by working with the right type of moments, but is usually unavoidable through the restriction of using only as many moments as there are parameters. This is because the reduction of a sample of size n to a “sample” of empirical moments of size d usually entails a loss of information.

This observation motivates the *generalized method of moments*. The idea is to reduce the sample to more “empirical moments” than there are parameters. Given a function $f: \mathbb{R}^{h+1} \rightarrow \mathbb{R}^e$, for $e > d$, with corresponding mean function $\phi(\theta) = E_\theta f(X_t, \dots, X_{t+h})$, there is no hope, in general, to solve an estimator $\hat{\theta}_n$ from the system of equations $\phi(\theta) = \hat{f}_n$, because these are $e > d$ equations in d unknowns. The *generalized method of moments* overcomes this by defining $\hat{\theta}_n$ as the minimizer of the quadratic form, for a given (possibly random) matrix \hat{V}_n ,

$$(11.3) \quad \theta \mapsto (\phi(\theta) - \hat{f}_n)^T \hat{V}_n (\phi(\theta) - \hat{f}_n).$$

Thus a generalized moment estimator tries to solve the system of equations $\phi(\theta) = \hat{f}_n$ as well as possible, where the discrepancy is measured through a certain quadratic form. The matrix \hat{V}_n weighs the influence of the different components of \hat{f}_n on the estimator $\hat{\theta}_n$, and is typically chosen dependent on the data to increase the efficiency of the estimator. We assume that \hat{V}_n is symmetric and positive-definite.

As $n \rightarrow \infty$ the estimator \hat{f}_n typically converges to its expectation $\phi(\theta_0) = E_{\theta_0} \bar{f}_n$ under the true parameter, which we shall denote by θ_0 for clarity. The quadratic form obtained by replacing \hat{f}_n in the criterion function (11.3) by its limit $\phi(\theta_0)$ is reduced to zero for θ equal to θ_0 . This is clearly the minimal value of the quadratic form, and the choice $\theta = \theta_0$ will be unique as soon as the map ϕ is one-to-one. This suggests that the generalized moment estimator $\hat{\theta}_n$ is asymptotically consistent. As for ordinary moment estimators, a rigorous justification of the consistency must take into account the properties of the function ϕ .

The distributional limit properties of a generalized moment estimator can be understood by linearizing the function ϕ around the true parameter. Insertion of the first order Taylor expansion $\phi(\theta) = \phi(\theta_0) + \phi'_{\theta_0}(\theta - \theta_0)$ into the quadratic form yields the approximate criterion

$$\begin{aligned} \theta &\mapsto (\hat{f}_n - \phi(\theta_0) - \phi'_{\theta_0}(\theta - \theta_0))^T \hat{V}_n (\hat{f}_n - \phi(\theta_0) - \phi'_{\theta_0}(\theta - \theta_0)) \\ &= \frac{1}{n} (Z_n - \phi'_{\theta_0} \sqrt{n}(\theta - \theta_0))^T \hat{V}_n (Z_n - \phi'_{\theta_0} \sqrt{n}(\theta - \theta_0)), \end{aligned}$$

for $Z_n = \sqrt{n}(\hat{f}_n - \phi(\theta_0))$. The sequence Z_n is typically asymptotically normally distributed, with mean zero. Minimization of this approximate criterion over $h = \sqrt{n}(\theta - \theta_0)$ is equivalent to minimizing the quadratic form $h \mapsto (Z_n - \phi'_{\theta_0} h)^T \hat{V}_n (Z_n - \phi'_{\theta_0} h)$, or equivalently minimizing the norm of the vector $Z_n - \phi'_{\theta_0} h$ over h in the Hilbert space \mathbb{R}^d with inner product defined by $\langle x, y \rangle = x^T \hat{V}_n y$. This comes down to projecting the vector Z_n onto the range of the linear map ϕ'_{θ_0} and hence by the projection theorem, Theorem 2.11, the minimizer $\tilde{h} = \sqrt{n}(\tilde{\theta} - \theta_0)$ is characterized by the orthogonality of the vector $Z_n - \phi'_{\theta_0} \tilde{h}$ to the range of ϕ'_{θ_0} . The algebraic expression of this orthogonality $(\phi'_{\theta_0})^T \hat{V}_n (Z_n - \phi'_{\theta_0} \tilde{h}) = 0$ can be written in the form

$$\sqrt{n}(\tilde{\theta}_n - \theta_0) = ((\phi'_{\theta_0})^T \hat{V}_n \phi'_{\theta_0})^{-1} (\phi'_{\theta_0})^T \hat{V}_n Z_n.$$

This readily gives the asymptotic normality of the sequence $\sqrt{n}(\tilde{\theta}_n - \theta_0)$, with mean zero and a somewhat complicated covariance matrix depending on ϕ'_{θ_0} , \hat{V}_n and the asymptotic

covariance matrix of Z_n . The minimizer $\hat{\theta}_n$ of the true criterion function (11.3) is not the same as $\hat{\theta}_n$, but Theorem 11.12 below give sufficient conditions for its having the same limiting distribution.

The best nonrandom weight matrices \hat{V}_n , in terms of minimizing the asymptotic covariance matrix of $\sqrt{n}(\hat{\theta}_n - \theta)$, is the inverse of the covariance matrix of Z_n . (Cf. Problem 11.11.) For our present situation this suggests to choose the matrix \hat{V}_n to be consistent for the inverse of the asymptotic covariance matrix of the sequence $Z_n = \sqrt{n}(\hat{f}_n - \phi(\theta_0))$. With this choice and the asymptotic covariance matrix denoted by Σ_{θ_0} , we may expect that

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N\left(0, ((\phi'_{\theta_0})^T \Sigma_{\theta_0}^{-1} \phi'_{\theta_0})^{-1}\right).$$

11.11 EXERCISE. Let Σ be a symmetric, positive-definite matrix and A a given matrix. Show that the matrix $(A^T V A)^{-1} A^T V \Sigma V^T A (A^T V A)^{-1}$ is minimized over symmetric, nonnegative-definite matrices V (where we say that $V \leq W$ if $W - V$ is nonnegative definite) for $V = \Sigma^{-1}$. [The given matrix is the covariance matrix of $\beta_A = (A^T V A)^{-1} A^T V Z$ for Z a random vector with the normal distribution with covariance matrix Σ . Show that $\text{Cov}(\beta_A - \beta_{\Sigma^{-1}}, \beta_{\Sigma^{-1}}) = 0$.]

The argument shows that the generalized moment estimator can be viewed as a weighted least squares estimators for regressing $Z - n = \sqrt{n}(\hat{f}_n - \phi(\theta_0))$ onto ϕ'_{θ_0} . If we use more initial moments to define \hat{f}_n and hence $\phi(\theta)$, then we add “observations” and corresponding rows to the design matrix ϕ'_{θ_0} , but keep the same parameter $\sqrt{n}(\theta - \theta_0)$. This suggests that the asymptotic efficiency of the optimally weighted generalized moment estimator increases if we use a longer vector of initial moments \hat{f}_n . In particular, the optimally weighted generalized moment estimator is more efficient than an ordinary moment estimator based on a subset of d of the initial moments. Thus, the generalized method of moments achieves the aim of using more information contained in the observations.

These arguments are based on asymptotic approximations. They are reasonably accurate for values of n that are large relative to the values of d and e , but should not be applied if d or e are large. In particular, it is illegal to push the preceding argument to its extreme and infer that it is fruitful to use as many initial moments as possible. Increasing the dimension of the vector \hat{f}_n indefinitely may contribute more “variability” to the criterion (and hence to the estimator), without increasing the information much (also depending on the accuracy of the estimator \hat{V}_n).

In the following theorem we make the preceding heuristic derivation of the asymptotics of generalized moment estimators rigorous. The theorem is a corollary of Theorems 3.17 and 3.18 on the asymptotics of general minimum contrast estimators. Consider generalized moment estimators as previously, defined as the point of minimum of a quadratic form of the type (11.3). In most cases the function $\phi(\theta)$ will be the expected value of the random vectors \hat{f}_n under the parameter θ , but this is not necessary. The following theorem is applicable as soon as $\phi(\theta)$ gives a correct “centering” to ensure that the sequence $\sqrt{n}(\hat{f}_n - \phi(\theta))$ converges to a limit distribution, and hence may also apply to nonstationary time series.

11.12 Theorem. Let \hat{V}_n be random matrices such that $\hat{V}_n \xrightarrow{P} V_0$ for some matrix V_0 . Assume that $\phi: \Theta \subset \mathbb{R}^d \rightarrow \mathbb{R}^e$ is differentiable at an inner point θ_0 of Θ with derivative ϕ'_{θ_0} such that the matrix $(\phi'_{\theta_0})^T V_0 \phi'_{\theta_0}$ is nonsingular and satisfies, for every $\delta > 0$,

$$(11.4) \quad \inf_{\theta: \|\theta - \theta_0\| > \delta} (\phi(\theta) - \phi(\theta_0))^T V_0 (\phi(\theta) - \phi(\theta_0)) > 0.$$

Assume either that V_0 is invertible or that the set $\{\phi(\theta): \theta \in \Theta\}$ is bounded. Finally, suppose that the sequence of random vectors $Z_n = \sqrt{n}(\hat{f}_n - \phi(\theta_0))$ is uniformly tight. If $\hat{\theta}_n$ are random vectors that minimize the criterion (11.3), then $\sqrt{n}(\hat{\theta}_n - \theta_0) = -((\phi'_{\theta_0})^T V_0 \phi'_{\theta_0})^{-1} V_0 Z_n + o_P(1)$.

Proof. We first prove that $\hat{\theta}_n \xrightarrow{P} \theta_0$ using Theorem 3.17, with the criterion functions

$$\begin{aligned} \mathbb{M}_n(\theta) &= \|\hat{V}_n^{1/2}(\hat{f}_n - \phi(\theta))\|, \\ M_n(\theta) &= \|\hat{V}_n^{1/2}(\phi(\theta_0) - \phi(\theta))\|. \end{aligned}$$

The squares of these functions are the criterion in (11.3) and the quadratic form (11.4), but with V_0 replaced by \hat{V}_n , respectively. By the triangle inequality $|\mathbb{M}_n(\theta) - M_n(\theta)| \leq \|\hat{V}_n^{1/2}(\hat{f}_n - \phi(\theta_0))\| \rightarrow 0$ in probability, uniformly in θ . Thus the first condition of Theorem 3.17 is satisfied. The second condition, that $\inf\{M_n(\theta): \|\theta - \theta_0\| > \delta\}$ is stochastically bounded away from zero for every $\delta > 0$, is satisfied by assumption (11.4) in the case that $\hat{V}_n = V_0$ is fixed. Because $\hat{V}_n \xrightarrow{P} V_0$, where V_0 is invertible or the set $\{\phi(\theta): \|\theta - \theta_0\| > \delta\}$ is bounded, it is also satisfied in the general case, in view of Exercise 11.13. This concludes the proof of consistency of $\hat{\theta}_n$.

For the proof of asymptotic normality we use Theorem 3.18 with the criterion functions \mathbb{M}_n and M_n redefined as the squares of the functions \mathbb{M}_n and M_n as used in the consistency proof (so that $\mathbb{M}_n(\theta)$ is the criterion function in (11.3)) and with the centering function M defined by

$$M(\theta) = (\phi(\theta) - \phi(\theta_0))^T V_0 (\phi(\theta) - \phi(\theta_0)).$$

It follows that, for any random sequence $\tilde{\theta}_n \xrightarrow{P} \theta_0$,

$$\begin{aligned} n(\mathbb{M}_n - M_n)(\tilde{\theta}_n) - n(\mathbb{M}_n - M_n)(\theta_0) &= -2\sqrt{n}(\phi(\tilde{\theta}_n) - \phi(\theta_0))^T \hat{V}_n Z_n, \\ &= -2\sqrt{n}(\tilde{\theta}_n - \theta_0)^T (\phi'_{\theta_0})^T \hat{V}_n Z_n + \sqrt{n}o_P(\tilde{\theta}_n - \theta_0), \end{aligned}$$

by the differentiability of ϕ at θ_0 . Together with the convergence of \hat{V}_n to V_0 , the differentiability of ϕ also gives that $M_n(\tilde{\theta}_n) - M(\tilde{\theta}_n) = o_P(\|\tilde{\theta}_n - \theta_0\|^2)$ for any sequence $\tilde{\theta}_n \xrightarrow{P} \theta_0$. Therefore, we may replace M_n by M in the left side of the preceding display, if we add an $o_P(n\|\tilde{\theta}_n - \theta_0\|^2)$ -term on the right. By a third application of the differentiability of ϕ , the function M permits the two-term Taylor expansion $M(\theta) = (\theta - \theta_0)^T W(\theta - \theta_0) + o(\|\theta - \theta_0\|^2)$, for $W = (\phi'_{\theta_0})^T V_0 \phi'_{\theta_0}$. Thus the conditions of Theorem 3.18 are satisfied and the proof of asymptotic normality is complete. ■

11.13 EXERCISE. Let V_n be a sequence of nonnegative-definite matrices such that $V_n \rightarrow V$ for a matrix V such that $\inf\{x^T V x : x \in C\} > 0$ for some set C . Show that:

- (i) If V is invertible, then $\liminf \inf\{x^T V_n x : x \in C\} > 0$.
- (ii) If C is bounded, then $\liminf \inf\{x^T V_n x : x \in C\} > 0$.
- (iii) The assertion of (i)-(ii) may fail without some additional assumption.

[Suppose that $x_n^T V_n x_n \rightarrow 0$. If V is invertible, then it follows that $x_n \rightarrow 0$. If the sequence x_n is bounded, then $x_n^T V x_n - x_n^T V_n x_n \rightarrow 0$. As counterexample let V_n be the matrices with eigenvectors proportional to $(n, 1)$ and $(-1, n)$ and eigenvalues 1 and 0, let $C = \{x : |x_1| > \delta\}$ and let $x_n = \delta(-1, n)$.]

11.2.2 Simulated Method of Moments

The implementation of the (generalized) method of moments requires that the expectations $\phi(\theta) = E_\theta f(X_t, \dots, X_{t+h})$ are available as functions of θ . In some models, such as AR or MA models, this causes no difficulty, but already in ARMA models the required analytical computations become complicated. Sometimes it is easy to simulate realizations of a time series, but hard to compute explicit formulas for moments. In this case the values $\phi(\theta)$ may be estimated stochastically at a grid of values of θ by simulating realizations of the given time series, taking in turn each of the grid points as the “true” parameter, and next computing the empirical moment for the simulated time series. If the grid is sufficiently dense and the simulations are sufficiently long, then the grid point for which the simulated empirical moment matches the empirical moment of the data is close to the moment estimator. Taking it to be the moment estimator is called the *simulated method of moments*.

11.2.3 Moving Average Processes

Suppose that $X_t - \mu = \sum_{j=0}^q \theta_j Z_{t-j}$ is a moving average process of order q . For simplicity of notation assume that $1 = \theta_0$ and define $\theta_j = 0$ for $j < 0$ or $j > q$. Then the auto-covariance function of X_t can be written in the form

$$\gamma_X(h) = \sigma^2 \sum_j \theta_j \theta_{j+h}.$$

Given observations X_1, \dots, X_n we can estimate $\gamma_X(h)$ by the sample auto-covariance function and next obtain estimators for $\sigma^2, \theta_1, \dots, \theta_q$ by solving the system of equations

$$\hat{\gamma}_n(h) = \hat{\sigma}^2 \sum_j \hat{\theta}_j \hat{\theta}_{j+h}, \quad h = 0, 1, \dots, q.$$

A solution of this system, which has $q + 1$ equations with $q + 1$ unknowns, does not necessarily exist, or may be nonunique. It cannot be derived in closed form, but must be determined numerically by an iterative method. Thus applying the method of moments for moving average processes is considerably more involved than for auto-regressive processes. The real drawback of this method is, however, that the moment estimators are less efficient than the least squares estimators that we discuss later in this chapter. Moment estimators are therefore at best only used as starting points for numerical procedures to compute other estimators.

11.14 Example (MA(1)). For the moving average process $X_t = Z_t + \theta Z_{t-1}$ the moment equations are

$$\gamma_X(0) = \sigma^2(1 + \theta^2), \quad \gamma_X(1) = \theta\sigma^2.$$

Replacing γ_X by $\hat{\gamma}_n$ and solving for σ^2 and θ yields the moment estimators

$$\hat{\theta}_n = \frac{1 \pm \sqrt{1 - 4\hat{\rho}_n^2(1)}}{2\hat{\rho}_n(1)}, \quad \hat{\sigma}^2 = \frac{\hat{\gamma}_n(1)}{\hat{\theta}_n}.$$

We obtain a real solution for $\hat{\theta}_n$ only if $|\hat{\rho}_n(1)| \leq 1/2$. Because the true auto-correlation $\rho_X(1)$ is contained in the interval $[-1/2, 1/2]$, it is reasonable to truncate the sample auto-correlation $\hat{\rho}_n(1)$ to this interval and then we always have some solution. If $|\hat{\rho}_n(1)| < 1/2$, then there are two solutions for $\hat{\theta}_n$, corresponding to the \pm sign. This situation will happen with probability tending to one if the true auto-correlation $\rho_X(1)$ is strictly contained in the interval $(-1/2, 1/2)$. From the two solutions, one solution has $|\hat{\theta}_n| < 1$ and corresponds to an invertible moving average process; the other solution has $|\hat{\theta}_n| > 1$. The existence of multiple solutions was to be expected in view of Theorem 8.30.

Assume that the true value $|\theta| < 1$, so that $\rho_X(1) \in (-1/2, 1/2)$ and

$$\theta = \frac{1 - \sqrt{1 - 4\rho_X^2(1)}}{2\rho_X(1)}.$$

Of course, we use the estimator $\hat{\theta}_n$ defined by the minus sign. Then $\hat{\theta}_n - \theta$ can be written as $\phi(\hat{\rho}_n(1)) - \phi(\rho_X(1))$ for the function ϕ given by

$$\phi(\rho) = \frac{1 - \sqrt{1 - 4\rho^2}}{2\rho}.$$

This function is differentiable on the interval $(-1/2, 1/2)$. By the Delta-method the limit distribution of the sequence $\sqrt{n}(\hat{\theta}_n - \theta)$ is the same as the limit distribution of the sequence $\phi'(\rho_X(1))\sqrt{n}(\hat{\rho}_n(1) - \rho_X(1))$. Using Theorem 5.9 we obtain, after a long calculation, that

$$\sqrt{n}(\hat{\theta}_n - \theta) \rightsquigarrow N\left(0, \frac{1 + \theta^2 + 4\theta^4 + \theta^6 + \theta^8}{(1 - \theta^2)^2}\right).$$

Thus, to a certain extent, the method of moments works: the moment estimator $\hat{\theta}_n$ converges at a rate of $1/\sqrt{n}$ to the true parameter. However, the asymptotic variance is large, in particular for $\theta \approx 1$. We shall see later that there exist estimators with asymptotic variance $1 - \theta^2$, which is smaller for every θ , and is particularly small for $\theta \approx 1$. \square

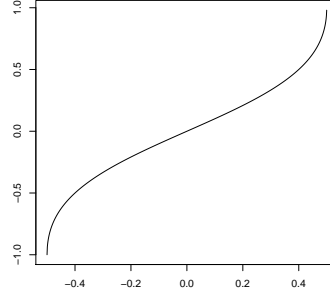

Figure 11.1. The function $\rho \mapsto (1 - \sqrt{1 - 4\rho^2})/(2\rho)$.

11.15 EXERCISE. Derive the formula for the asymptotic variance, or at least convince yourself that you know how to get it.

The asymptotic behaviour of the moment estimators for moving averages of order higher than 1 can be analysed, as in the preceding example, by the Delta-method as well. Define $\phi: \mathbb{R}^{q+1} \rightarrow \mathbb{R}^{q+1}$ by

$$(11.5) \quad \phi \begin{pmatrix} \sigma^2 \\ \theta_1 \\ \vdots \\ \theta_q \end{pmatrix} = \sigma^2 \begin{pmatrix} \sum_j \theta_j^2 \\ \sum_j \theta_j \theta_{j+1} \\ \vdots \\ \sum_j \theta_j \theta_{j+q} \end{pmatrix}.$$

Then the moment estimators and true parameters satisfy

$$\begin{pmatrix} \hat{\sigma}^2 \\ \hat{\theta}_1 \\ \vdots \\ \hat{\theta}_q \end{pmatrix} = \phi^{-1} \begin{pmatrix} \hat{\gamma}_n(0) \\ \hat{\gamma}_n(1) \\ \vdots \\ \hat{\gamma}_n(q) \end{pmatrix}, \quad \begin{pmatrix} \sigma^2 \\ \theta_1 \\ \vdots \\ \theta_q \end{pmatrix} = \phi^{-1} \begin{pmatrix} \gamma_X(0) \\ \gamma_X(1) \\ \vdots \\ \gamma_X(q) \end{pmatrix}.$$

The joint limit distribution of the sequences $\sqrt{n}(\hat{\gamma}_n(h) - \gamma_X(h))$ is known from Theorem 5.8. Therefore, the limit distribution of the moment estimators $\hat{\sigma}^2, \hat{\theta}_1, \dots, \hat{\theta}_q$ follows by the Delta-method, provided the map ϕ^{-1} is differentiable at $(\gamma_X(0), \dots, \gamma_X(q))$.

Practical and theoretical complications arise from the fact that the moment equations may have zero or multiple solutions, as illustrated in the preceding example. This difficulty disappears if we insist on an invertible representation of the moving average process, i.e. require that the polynomial $1 + \theta_1 z + \dots + \theta_q z^q$ has no roots in the complex unit disc. This follows by the following lemma, whose proof also contains an algorithm to compute the moment estimators numerically.

11.16 Lemma. Let $\Theta \subset \mathbb{R}^q$ be the set of all vectors $(\theta_1, \dots, \theta_q)$ such that all roots of $1 + \theta_1 z + \dots + \theta_q z^q$ are outside the unit circle. Then the map $\phi: \mathbb{R}^+ \times \Theta \rightarrow \mathbb{R}^{q+1}$ in (11.5) is one-to-one and continuously differentiable. Furthermore, the map ϕ^{-1} is differentiable at every point $\phi(\sigma^2, \theta_1, \dots, \theta_q)$ for which the roots of $1 + \theta_1 z + \dots + \theta_q z^q$ are distinct.

* **Proof.** Abbreviate $\gamma_h = \gamma_X(h)$. The system of equations $\sigma^2 \sum_j \theta_j \theta_{j+h} = \gamma_h$ for $h = 0, \dots, q$ implies that

$$\sum_{h=-q}^q \gamma_h z^h = \sigma^2 \sum_h \sum_j \theta_j \theta_{j+h} z^h = \sigma^2 \theta(z^{-1}) \theta(z).$$

For any $h \geq 0$ the function $z^h + z^{-h}$ can be expressed as a polynomial of degree h in $w = z + z^{-1}$. For instance, $z^2 + z^{-2} = w^2 - 2$ and $z^3 + z^{-3} = w^3 - 3w$. The case of general h can be treated by induction, upon noting that by rearranging Newton's binomial formula

$$z^{h+1} + z^{-h-1} - w^{h+1} = - \binom{h+1}{(h+1)/2} - \sum_{j \neq 0} \binom{h+1}{(h+1-j)/2} (z^j + z^{-j}).$$

Thus the left side of the preceding display can be written in the form

$$\gamma_0 + \sum_{h=1}^q \gamma_j (z^j + z^{-j}) = a_0 + a_1 w + \dots + a_q w^q,$$

for certain coefficients (a_0, \dots, a_q) . Let w_1, \dots, w_q be the zeros of the polynomial on the right, and for each j let η_j and η_j^{-1} be the solutions of the quadratic equation $z + z^{-1} = w_j$. Choose $|\eta_j| \geq 1$. Then we can rewrite the right side of the preceding display as

$$a_q \prod_{j=1}^q (z + z^{-1} - w_j) = a_q (z - \eta_j)(\eta_j - z^{-1}) \eta_j^{-1}.$$

On comparing this to the first display of the proof, we see that η_1, \dots, η_q are the zeros of the polynomial $\theta(z)$. This allows us to construct a map

$$(\gamma_0, \dots, \gamma_q) \mapsto (a_0, \dots, a_q) \mapsto (w_1, \dots, w_q, a_q) \mapsto (\eta_1, \dots, \eta_q, a_q) \mapsto (\theta_1, \dots, \theta_q, \sigma^2).$$

If restricted to the range of ϕ this is exactly the map ϕ^{-1} . It is not hard to see that the first and last step in this decomposition of ϕ^{-1} are analytic functions. The two middle steps concern mapping coefficients of polynomials into their zeros.

For $\alpha = (\alpha_0, \dots, \alpha_q) \in \mathbb{C}^{q+1}$ let $p_\alpha(w) = \alpha_0 + \alpha_1 w + \dots + \alpha_q w^q$. By the implicit function theorem for functions of several complex variables we can show the following. If for some α the polynomial p_α has a root of order 1 at a point w_α , then there exists neighbourhoods U_α and V_α of α and w_α such that for every $\beta \in U_\alpha$ the polynomial p_β has exactly one zero $w_\beta \in V_\alpha$ and the map $\beta \mapsto w_\beta$ is analytic on U_α . Thus, under the assumption that all roots are of multiplicity one, the roots can be viewed as analytic functions of the coefficients. If θ has distinct roots, then η_1, \dots, η_q are of multiplicity one and hence so are w_1, \dots, w_q . In that case the map is analytic. ■

* 11.2.4 Moment Estimators for ARMA Processes

If $X_t - \mu$ is a stationary ARMA process satisfying $\phi(B)(X_t - \mu) = \theta(B)Z_t$, then

$$\text{cov}(\phi(B)(X_t - \mu), X_{t-k}) = E(\theta(B)Z_t)X_{t-k}.$$

If $X_t - \mu$ is a causal, stationary ARMA process, then the right side vanishes for $k > q$. Working out the left side, we obtain the equations

$$\gamma_X(k) - \phi_1\gamma_X(k-1) - \cdots - \phi_p\gamma_X(k-p) = 0, \quad k > q.$$

For $k = q+1, \dots, q+p$ this leads to the system

$$\begin{pmatrix} \gamma_X(q) & \gamma_X(q-1) & \cdots & \gamma_X(q-p+1) \\ \gamma_X(q+1) & \gamma_X(q) & \cdots & \gamma_X(q-p+2) \\ \vdots & \vdots & & \vdots \\ \gamma_X(q+p-1) & \gamma_X(q+p-2) & \cdots & \gamma_X(q) \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \\ \vdots \\ \phi_p \end{pmatrix} = \begin{pmatrix} \gamma_X(q+1) \\ \gamma_X(q+2) \\ \vdots \\ \gamma_X(q+p) \end{pmatrix}.$$

These are the *Yule-Walker equations* for general stationary ARMA processes and may be used to obtain estimators $\hat{\phi}_1, \dots, \hat{\phi}_p$ of the auto-regressive parameters in the same way as for auto-regressive processes: we replace γ_X by $\hat{\gamma}_n$ and solve for ϕ_1, \dots, ϕ_p .

Next we apply the method of moments for moving averages to the time series $Y_t = \theta(B)Z_t$ to obtain estimators for the parameters $\sigma^2, \theta_1, \dots, \theta_q$. Because also $Y_t = \phi(B)(X_t - \mu)$ we can write the covariance function γ_Y in the form

$$\gamma_Y(h) = \sum_i \sum_j \tilde{\phi}_i \tilde{\phi}_j \gamma_X(h+i-j), \quad \text{if } \phi(z) = \sum_j \tilde{\phi}_j z^j.$$

Let $\hat{\gamma}_Y(h)$ be the estimators obtained by replacing the unknown parameters $\tilde{\phi}_j = -\phi_j$ and $\gamma_X(h)$ by their moment estimators and sample moments, respectively. Next we solve $\hat{\sigma}^2, \hat{\theta}_1, \dots, \hat{\theta}_q$ from the system of equations

$$\hat{\gamma}_Y(h) = \hat{\sigma}^2 \sum_j \hat{\theta}_j \hat{\theta}_{j+h}, \quad h = 0, 1, \dots, q.$$

As is explained in the preceding section, if $X_t - \mu$ is invertible, then the solution is unique, with probability tending to one, if the coefficients $\theta_1, \dots, \theta_q$ are restricted to give an invertible stationary ARMA process.

The resulting estimators $(\hat{\sigma}^2, \hat{\theta}_1, \dots, \hat{\theta}_q, \hat{\phi}_1, \dots, \hat{\phi}_p)$ can be written as a function of $(\hat{\gamma}_n(0), \dots, \hat{\gamma}_n(q+p))$. The true values of the parameters can be written as the same function of the vector $(\gamma_X(0), \dots, \gamma_X(q+p))$. In principle, under some conditions, the limit distribution of the estimators can be obtained by the Delta-method.

* 11.2.5 Stochastic Volatility Models

In the stochastic volatility model discussed in Section 10.4 an observation X_t is defined as $X_t = \sigma_t Z_t$ for $\log \sigma_t$ a stationary auto-regressive process satisfying $\log \sigma_t = \alpha + \phi \log \sigma_{t-1} + \sigma V_{t-1}$, and (V_t, Z_t) an i.i.d. sequence of bivariate normal vectors with mean zero, unit variances and correlation δ . Thus the model is parameterized by four parameters $\alpha, \phi, \sigma, \delta$.

The series X_t is a white noise series and hence we cannot use the auto-covariances $\gamma_X(h)$ at lags $h \neq 0$ to construct moment estimators. Instead, we might use higher marginal moments or auto-covariances of powers of the series. In particular, it is computed in Section 10.4 that

$$\begin{aligned} E|X_t| &= \exp\left(\frac{1}{2} \frac{\sigma^2}{1-\phi^2} + \frac{\alpha}{1-\phi}\right) \sqrt{\frac{2}{\pi}}, \\ E|X_t|^2 &= \exp\left(\frac{1}{2} \frac{4\sigma^2}{1-\phi^2} + \frac{2\alpha}{1-\phi}\right), \\ E|X_t|^3 &= \exp\left(\frac{1}{2} \frac{9\sigma^2}{1-\phi^2} + \frac{3\alpha}{1-\phi}\right) 2\sqrt{\frac{2}{\pi}}, \\ EX_t^4 &= \exp\left(\frac{8\sigma^2}{1-\phi^2} + \frac{4\alpha}{1-\phi}\right) 3, \\ \rho_{X^2}(1) &= \frac{(1 + 4\delta^2\sigma^2)e^{4\sigma^2\phi/(1-\phi^2)} - 1}{3e^{4\sigma^2/(1-\phi^2)} - 1}, \\ \rho_{X^2}(2) &= \frac{(1 + 4\delta^2\sigma^2\phi^2)e^{4\sigma^2\phi^2/(1-\phi^2)} - 1}{3e^{4\sigma^2/(1-\phi^2)} - 1}, \\ \rho_{X^2}(3) &= \frac{(1 + 4\delta^2\sigma^2\phi^4)e^{4\sigma^2\phi^3/(1-\phi^2)} - 1}{3e^{4\sigma^2/(1-\phi^2)} - 1}. \end{aligned}$$

We can use a selection of these moments to define moment estimators, or use some or all of them to define generalized moments estimators. Because the functions on the right side are complicated, this requires some effort, but it is feasible.[†]

11.3 Least Squares Estimators

For auto-regressive processes the method of least squares is directly suggested by the structural equation defining the model, but it can also be derived from the prediction problem. The second point of view is deeper and can be applied to general time series.

A *least squares estimator* is based on comparing the predicted value of an observation X_t based on the preceding observations to the actually observed value X_t . Such a prediction $\Pi_{t-1}X_t$ will generally depend on the underlying parameter θ of the model,

[†] See Taylor (1986).

which we shall make visible in the notation by writing it as $\Pi_{t-1}X_t(\theta)$. The index $t-1$ of Π_{t-1} indicates that $\Pi_{t-1}X_t(\theta)$ is a function of X_1, \dots, X_{t-1} (and the parameter) only. By convention we define $\Pi_0X_1 = 0$. A *weighted least squares estimator*, with inverse weights $w_t(\theta)$, is defined as the minimizer, if it exists, of the function

$$(11.6) \quad \theta \mapsto \sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\theta))^2}{w_t(\theta)}.$$

This expression depends only on the observations X_1, \dots, X_n and the unknown parameter θ and hence is an “observable criterion function”. The idea is that using the “true” parameter should yield the “best” predictions. The weights $w_t(\theta)$ could be chosen equal to one, but are generally chosen to increase the efficiency of the resulting estimator.

This least squares principle is intuitively reasonable for any sense of prediction, in particular both for linear and nonlinear prediction. For nonlinear prediction we set $\Pi_{t-1}X_t(\theta)$ equal to the conditional expectation $E_\theta(X_t | X_1, \dots, X_{t-1})$, an expression that may or may not be easy to derive analytically.

For linear prediction, if we assume that the time series X_t is centered at mean zero, we set $\Pi_{t-1}X_t(\theta)$ equal to the linear combination $\beta_1X_{t-1} + \dots + \beta_{t-1}X_1$ that minimizes

$$(\beta_1, \dots, \beta_{t-1}) \mapsto E_\theta(X_t - (\beta_1X_{t-1} + \dots + \beta_{t-1}X_1))^2, \quad \beta_1, \dots, \beta_t \in \mathbb{R}.$$

In Chapter 2 the coefficients of the best linear predictor are expressed in the auto-covariance function γ_X by the prediction equations (2.4). Thus the coefficients β_t depend on the parameter θ of the underlying model through the auto-covariance function. Hence the least squares estimators using linear predictors can also be viewed as moment estimators.

The difference $X_t - \Pi_{t-1}X_t(\theta)$ between the true value and its prediction is called *innovation*. Its second moment

$$v_t(\theta) = E_\theta(X_t - \Pi_{t-1}X_t(\theta))^2$$

is called the (square) *prediction error* at time $t-1$. The weights $w_t(\theta)$ are often chosen equal to the prediction errors $v_t(\theta)$ in order to ensure that the terms of the sum of squares contribute “equal” amounts of information.

For both linear and nonlinear predictors the innovations $X_1 - \Pi_0X_1(\theta), X_2 - \Pi_1X_2(\theta), \dots, X_n - \Pi_{n-1}X_n(\theta)$ are uncorrelated random variables. This orthogonality suggests that the terms of the sum contribute “additive information” to the criterion, which should be good. It also shows that there is usually no need to replace the sum of squares by a more general quadratic form, which would be the standard approach in ordinary least squares estimation.

Whether the sum of squares indeed possesses a (unique) point of minimum $\hat{\theta}$ and whether this constitutes a good estimator of the parameter θ depends on the statistical model for the time series. Moreover, this model determines the feasibility of computing the point of minimum given the data. Auto-regressive and GARCH processes provide a positive and a negative example.

11.17 Example (Autoregression). A mean-zero, causal, stationary, auto-regressive process of order p is modelled through the parameter $\theta = (\sigma^2, \phi_1, \dots, \phi_p)$. For $t \geq p$ the best linear predictor is given by $\Pi_{t-1}X_t = \phi_1 X_{t-1} + \dots + \phi_p X_{t-p}$ and the prediction error is $v_t = EZ_t^2 = \sigma^2$. For $t < p$ the formulas are more complicated, but could be obtained in principle.

The weighted sum of squares with weights $w_t = v_t$ reduces to

$$\sum_{t=1}^p \frac{(X_t - \Pi_{t-1}X_t(\phi_1, \dots, \phi_p))^2}{v_t(\sigma^2, \phi_1, \dots, \phi_p)} + \sum_{t=p+1}^n \frac{(X_t - \phi_1 X_{t-1} - \dots - \phi_p X_{t-p})^2}{\sigma^2}.$$

Because the first term, consisting of p of the n terms of the sum of squares, possesses a complicated form, it is often dropped from the sum of squares. Then we obtain exactly the sum of squares considered in Section 11.1, but with \bar{X}_n replaced by 0 and divided by σ^2 . For large n the difference between the sums of squares and hence between the two types of least squares estimators should be negligible.

Another popular strategy to simplify the sum of squares is to act as if the “observations” $X_0, X_{-1}, \dots, X_{-p+1}$ are available and to redefine $\Pi_{t-1}X_t$ for $t = 1, \dots, p$ accordingly. This is equivalent to dropping the first term and letting the sum in the second term start at $t = 1$ rather than at $t = p + 1$. To implement the estimator we must now choose numerical values for the missing observations $X_0, X_{-1}, \dots, X_{-p+1}$; zero is a common choice.

The least squares estimators for ϕ_1, \dots, ϕ_p , being (almost) identical to the Yule-Walker estimators, are \sqrt{n} -consistent and asymptotically normal. However, the least squares criterion does not lead to a useful estimator for σ^2 : minimization over σ^2 leads to $\sigma^2 = \infty$ and this is obviously not a good estimator. A more honest conclusion is that the least squares criterion as posed originally fails for auto-regressive processes, since minimization over the full parameter $\theta = (\sigma^2, \phi_1, \dots, \phi_p)$ leads to a zero sum of squares for $\sigma^2 = \infty$ and arbitrary (finite) values of the remaining parameters. The method of least squares works only for the subparameter (ϕ_1, \dots, ϕ_p) if we first drop σ^2 from the sum of squares. \square

11.18 Example (GARCH). A GARCH process is a martingale difference series and hence the one-step predictions $\Pi_{t-1}X_t(\theta)$ are identically zero. Consequently, the weighted least squares sum, with weights equal to the prediction errors, reduces to

$$\sum_{t=1}^n \frac{X_t^2}{v_t(\theta)}.$$

Minimizing this criterion over θ is equivalent to maximizing the prediction errors $v_t(\theta)$. It is intuitively clear that this does not lead to reasonable estimators.

One alternative is to apply the least squares method to the squared series X_t^2 . This satisfies an ARMA equation in view of (9.3). (Note however that the innovations in that equation are also dependent on the parameter.)

The best fix of the least squares method is to augment the least squares criterion to the Gaussian likelihood, as discussed in Chapter 13. \square

So far the discussion in this section has assumed implicitly that the mean value $\mu = EX_t$ of the time series is zero. If this is not the case, then we apply the preceding to the time series $X_t - \mu$ instead of to X_t . Then the parameter μ will show up in the least squares criterion. To define estimators we can either replace the unknown value μ by the sample mean \bar{X}_n and minimize the sum of squares with respect to the remaining parameters, or perform a joint minimization over all parameters.

Least squares estimators can rarely be written in closed form, the case of stationary auto-regressive processes being an exception, but iterative algorithms for an approximate calculation are implemented in many computer packages. Newton-type algorithms provide one possibility. The best linear predictions $\Pi_{t-1}X_t(\theta)$ are often computed recursively in t (for a grid of values θ), for instance with the help of a state space representation of the time series and the Kalman filter.

The method of least squares is closely related to Gaussian likelihood, as discussed in Chapter 13. Gaussian likelihood is perhaps more fundamental than the method of least squares. For this reason we restrict further discussion of the method of least squares to ARMA processes.

11.3.1 ARMA Processes

The method of least squares works well for estimating the regression and moving average parameters $(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$ of ARMA processes, provided that we perform the minimization for a fixed value of the parameter σ^2 .

In general, if some parameter, such as σ^2 for ARMA processes, enters the covariance function as a multiplicative factor, then the best linear predictor $\Pi_t X_{t+1}$ is free from this parameter, by the prediction equations (2.4). On the other hand, the prediction error $v_{t+1} = \gamma_X(0) - (\beta_1, \dots, \beta_t)\Gamma_t(\beta_1, \dots, \beta_t)^T$ (where β_1, \dots, β_t are the coefficients of the best linear predictor) contains such a parameter as a multiplicative factor. It follows that the inverse of the parameter will enter the least squares criterion (11.6) as a multiplicative factor. Thus the least squares method does not yield an estimator for this parameter, but we can just omit it and minimize the criterion over the remaining parameters.

In particular, in the case of ARMA processes least squares estimators for $(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$ can be defined as the minimizers of, for $\tilde{v}_t = \sigma^{-2}v_t$,

$$\sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q))^2}{\tilde{v}_t(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)}.$$

This is a complicated function of the parameters. However, for a fixed value of $(\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$ it can be computed using the state space representation of an ARMA process and the Kalman filter. A grid search or iteration method can do the rest.

11.19 Theorem. *Let X_t be a causal and invertible stationary ARMA(p, q) process relative to an i.i.d. sequence Z_t with finite fourth moments. Then the least squares estimators satisfy*

$$\sqrt{n} \left(\begin{pmatrix} \hat{\phi}_p \\ \hat{\theta}_q \end{pmatrix} - \begin{pmatrix} \vec{\phi}_p \\ \vec{\theta}_q \end{pmatrix} \right) \rightsquigarrow N(0, \sigma^2 J_{\vec{\phi}_p, \vec{\theta}_q}^{-1}),$$

where $J_{\vec{\phi}_p, \vec{\theta}_q}$ is the covariance matrix of $(U_{-1}, \dots, U_{-p}, V_{-1}, \dots, V_{-q})$ for stationary autoregressive processes U_t and V_t satisfying $\phi(B)U_t = \theta(B)V_t = Z_t$.

Proof. The proof of this theorem is long and technical. See e.g. Brockwell and Davis (1991), pages 375–396, Theorem 10.8.2. ■

11.20 Example (MA(1)). The least squares estimator $\hat{\theta}_n$ for θ in the moving average process $X_t = Z_t + \theta Z_{t-1}$ with $|\theta| < 1$ possesses asymptotic variance equal to $\sigma^2 / \text{var } V_{-1}$, where V_t is the stationary solution to the equation $\theta(B)V_t = Z_t$. Note that V_t is an autoregressive process of order 1, not a moving average!

As we have seen before (see Example 1.8) the process V_t possesses the representation $V_t = \sum_{j=0}^{\infty} (-\theta)^j Z_{t-j}$ and hence $\text{var } V_t = \sigma^2 / (1 - \theta^2)$ for every t .

Thus the sequence $\sqrt{n}(\hat{\theta}_n - \theta)$ is asymptotically normally distributed with mean zero and variance equal to $1 - \theta^2$. This is always smaller than the asymptotic variance of the moment estimator, obtained in Example 11.14. □

11.21 EXERCISE. Find the asymptotic covariance matrix of the sequence $\sqrt{n}(\hat{\phi}_n - \phi, \hat{\theta}_n - \theta)$ for $(\hat{\phi}_n, \hat{\theta}_n)$ the least squares estimators for the stationary, causal, invertible ARMA process satisfying $X_t = \phi X_{t-1} + Z_t + \theta Z_{t-1}$.

12

Spectral Estimation

In this chapter we study nonparametric estimators of the spectral density and spectral distribution of a stationary time series. As in Chapter 5 “nonparametric” means that no a-priori structure of the series is assumed, apart from stationarity.

If a well-fitting model is available, then spectral estimators suited to this model are an alternative to the methods of this chapter. For instance, the spectral density of a stationary ARMA process can be expressed in the parameters $\sigma^2, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$ of the model (see Section 8.5) and hence can be estimated by plugging in estimators for the parameters. If the ARMA model is appropriate, this should lead to better estimators than the nonparametric estimators discussed in this chapter. We do not further discuss this type of estimator.

Let the observations X_1, \dots, X_n be the values at times $1, \dots, n$ of a stationary time series X_t , and let $\hat{\gamma}_n$ be their sample auto-covariance function. In view of the definition of the spectral density $f_X(\lambda)$, a natural estimator is

$$(12.1) \quad \hat{f}_{n,r}(\lambda) = \frac{1}{2\pi} \sum_{|h| < r} \hat{\gamma}_n(h) e^{-ih\lambda}.$$

Whereas $f_X(\lambda)$ is defined as an infinite series, the estimator $\hat{f}_{n,r}$ is truncated at its r th term. Because the estimators $\hat{\gamma}_n(h)$ are defined only for $|h| < n$ and there is no hope of estimating the auto-covariances $\gamma_X(h)$ for lags $|h| \geq n$, we must choose $r \leq n$. Because the estimators $\hat{\gamma}_n(h)$ are unreliable for $|h| \approx n$, it may be wise to choose r much smaller than n . We shall see that a good choice of r depends on the smoothness of the spectral density and also on which aspect of the spectrum is of interest. For estimating $f_X(\lambda)$ at a point, values of r such as n^α for some $\alpha \in (0, 1)$ may be appropriate, whereas for estimating the spectral distribution function (i.e. areas under f_X) the choice $r = n$ works well.

In any case, since the covariances of lags $|h| \geq n$ can never be estimated from the data, nonparametric estimation of the spectrum is hopeless, unless one is willing to assume that expressions such as $\sum_{|h| \geq n} |\gamma_X(h)|$ are small. In Section 12.3 ahead we relate this tail series to the smoothness of the spectral density $\lambda \mapsto f_X(\lambda)$. If this function is

several times differentiable, then the auto-covariance function decreases fast to zero, and nonparametric estimation is feasible.

12.1 Finite Fourier Transform

The finite Fourier transform is a useful tool in spectral analysis, both for theory and practice. The practical use comes from the fact that it can be computed efficiently by a clever algorithm, the *Fast Fourier Transform* (FFT). While a naive computation would require $O(n^2)$ multiplications and summations, the FFT needs only $O(n \log n)$ operations.[‡]

The *finite Fourier transform* of an arbitrary sequence x_1, \dots, x_n of complex numbers is defined as the function $\lambda \mapsto d_x(\lambda)$ given by

$$d_x(\lambda) = \frac{1}{\sqrt{n}} \sum_{t=1}^n x_t e^{-i\lambda t}, \quad \lambda \in (-\pi, \pi].$$

In other words, the function $\sqrt{n/2\pi} d_x(\lambda)$ is the Fourier series corresponding to the coefficients $\dots, 0, 0, x_1, x_2, \dots, x_n, 0, 0, \dots$. The inversion formula (or a short calculation) shows that

$$x_t = \frac{\sqrt{n}}{2\pi} \int_{-\pi}^{\pi} e^{it\lambda} d_x(\lambda) d\lambda, \quad t = 1, 2, \dots, n.$$

Thus there is a one-to-one relationship between the numbers x_1, \dots, x_n and the function d_x . We may view the function d_x as “encoding” the numbers x_1, \dots, x_n .

Encoding n numbers by a function on the interval $(-\pi, \pi]$ is rather inefficient. At closer inspection the numbers x_1, \dots, x_n can also be recovered from the values of d_x on the grid

$$\dots, -\frac{4\pi}{n}, -\frac{2\pi}{n}, 0, \frac{2\pi}{n}, \frac{4\pi}{n}, \dots \subset (-\pi, \pi].$$

These n points are called the *natural frequencies* at time n . (The value 0 is always a natural frequency; for odd n there are $(n-1)/2$ positive and negative natural frequencies, situated symmetrically about 0; for even n the value π is a natural frequency, and the remaining natural frequencies are $n/2 - 1$ points in $(0, \pi)$ and their reflections.)

12.1 Lemma. *If d_x is the finite Fourier transform of $x_1, \dots, x_n \in \mathbb{C}$, then*

$$x_t = \frac{1}{\sqrt{n}} \sum_j d_x(\lambda_j) e^{it\lambda_j}, \quad t = 1, 2, \dots, n,$$

where the sum is computed over the natural frequencies $\lambda_j \in (-\pi, \pi]$ at time n .

Proof. For every of the natural frequencies λ_j define a vector

$$e_j = \frac{1}{\sqrt{n}} (e^{i\lambda_j}, e^{i2\lambda_j}, \dots, e^{in\lambda_j})^T.$$

[‡] See e.g. Brockwell and Davis, Chapter 10 for a discussion.

It is straightforward to check that the n vectors e_j form an orthonormal set in \mathbb{C}^n and hence a basis. Thus the vector $x = (x_1, \dots, x_n)^T$ can be written as $x = \sum_j \langle x, e_j \rangle e_j$. Now $\langle x, e_j \rangle = d_x(\lambda_j)$ and the lemma follows. ■

The proof of the preceding lemma shows how the numbers $d_x(\lambda_j)$ can be interpreted. View the coordinates of the vector $x = (x_1, \dots, x_n)$ as the values of a signal at the time instants $1, 2, \dots, n$. Similarly, view the coordinates of the vector e_j as the values of the trigonometric signal $t \mapsto n^{-1/2} e^{it\lambda_j}$ of frequency λ_j at these time instants. By the preceding lemma the signal x can be written as a linear combination of the signals e_j . The value $|d_x(\lambda_j)|$ is the weight of signal e_j , and hence of frequency λ_j , in x .

12.2 EXERCISE. How is the weight of frequency 0 expressed in (x_1, \dots, x_n) ?

12.3 EXERCISE. Show that $d_{(\mu, \mu, \dots, \mu)}(\lambda_j) = 0$ for every nonzero natural frequency λ_j and every $\mu \in \mathbb{C}$. Conclude that $d_{x - \bar{x}_n}(\lambda_j) = d_x(\lambda_j)$ for every $\lambda_j \neq 0$, where $x - \bar{x}$ denotes the numbers $x_1 - \bar{x}, \dots, x_n - \bar{x}$. [Hint: you can compute this explicitly, or use that $d_x(\lambda_j) = \langle x, e_j \rangle$ as in the proof of the preceding lemma, for any x .]

12.2 Periodogram

The *periodogram* of a sequence of observations X_1, \dots, X_n is defined as the function $\lambda \mapsto I_n(\lambda)$ given by

$$I_n(\lambda) = \frac{1}{2\pi} |d_X(\lambda)|^2 = \frac{1}{2\pi n} \left| \sum_{t=1}^n X_t e^{-it\lambda} \right|^2.$$

We write $I_{n,X}$ if the dependence on X_1, \dots, X_n needs to be stressed.

In view of the interpretation of the finite Fourier transform in the preceding section $I_n(\lambda)$ is the square of the weight of frequency λ in the signal X_1, \dots, X_n . Because the spectral density $f_X(\lambda)$ at λ can be interpreted as the variance of the component of frequency λ in the time series X_t , the function I_n may appear to be a reasonable estimator of the function f_X . We shall see that the expected value of $I_n(\lambda)$ is indeed close to $f_X(\lambda)$, but $I_n(\lambda)$ is not a good estimator of $f_X(\lambda)$. Because better estimator can be derived from the periodogram, it is still of interest to study its properties.

By evaluating the square in its definition and rearranging the resulting double sum, the periodogram can be rewritten in the form (if x_1, \dots, x_n are real)

$$(12.2) \quad I_n(\lambda) = \frac{1}{2\pi} \sum_{|h| < n} \left(\frac{1}{n} \sum_{t=1}^{n-|h|} X_{t+|h|} X_t \right) e^{-ih\lambda}.$$

For natural frequencies $\lambda_j \neq 0$ we have that $d_{-\mu, \dots, \mu}(\lambda_j) = 0$ for every μ , in particular for $\mu = \bar{X}_n$. This implies that $I_{n,X}(\lambda_j) = I_{n, X - \bar{X}_n}(\lambda_j)$ and hence

$$(12.3) \quad I_n(\lambda_j) = \frac{1}{2\pi} \sum_{|h| < n} \hat{\gamma}_n(h) e^{-ih\lambda_j}, \quad \lambda_j \in \frac{2\pi}{n}\mathbb{Z} - \{0\}.$$

This is exactly the estimator $\hat{f}_{n,n}(\lambda)$ given in (12.1), with $r = n$. As noted before, we should expect this estimator to be unreliable as an estimator of $f_X(\lambda)$, because of the imprecision of the estimators $\hat{\gamma}_n(h)$ for lags $|h|$ close to n .

Under the assumption that the time series X_t is stationary, we can compute the mean of the periodogram, for $\lambda \neq 0$, as

$$\begin{aligned} \mathbb{E}I_n(\lambda) &= \frac{1}{2\pi} \mathbb{E}|d_X(\lambda)|^2 = \frac{1}{2\pi} \text{var } d_X(\lambda) + \frac{1}{2\pi} |\mathbb{E}d_X(\lambda)|^2 \\ &= \frac{1}{2\pi n} \sum_{s=1}^n \sum_{t=1}^n \text{cov}(X_s, X_t) e^{i\lambda(s-t)} + \frac{1}{2\pi n} \left| \sum_{t=1}^n \mathbb{E}X_t e^{-i\lambda t} \right|^2 \\ &= \frac{1}{2\pi} \sum_{|h| < n} \left(1 - \frac{|h|}{n}\right) \gamma_X(h) e^{-i\lambda h} + \frac{\mu^2}{2\pi n} \left| \frac{1 - e^{-i\lambda n}}{1 - e^{-i\lambda}} \right|^2. \end{aligned}$$

The second term on the far right is of the order $O(1/n)$ for every $\lambda \neq 0$ (and $\lambda \in (-\pi, \pi)$) and even vanishes for every natural frequency $\lambda_j \neq 0$. Under the condition that $\sum_h |\gamma_X(h)| < \infty$, the first term converges to $f_X(\lambda)$ as $n \rightarrow \infty$, by the dominated convergence theorem. We conclude that the periodogram is *asymptotically unbiased* for estimating the spectral density: $\mathbb{E}I_n(\lambda) \rightarrow f_X(\lambda)$. This is a good property.

However, the periodogram is not a consistent estimator for $f_X(\lambda)$: the following theorem shows that $I_n(\lambda)$ is asymptotically exponentially distributed with mean $f_X(\lambda)$, whence we do *not* have that $I_n(\lambda) \xrightarrow{P} f_X(\lambda)$. Using the periodogram as an estimator of $f_X(\lambda)$ is asymptotically equivalent to estimating $f_X(\lambda)$ using a single observation from an exponential distribution with mean $f_X(\lambda)$. This is disappointing, because we should hope that observing the time series X_t long enough will enable us to estimate its spectral density with arbitrary precision. The periodogram does not fulfill this hope, as it keeps fluctuating around the target value $f_X(\lambda)$. Apparently, it does not effectively use the information available in the observations X_1, \dots, X_n .

12.4 Theorem. Let $X_t = \sum_{j=-\infty}^{\infty} \psi_j Z_{t-j}$ for an i.i.d. sequence Z_t with mean zero and finite second moment and coefficients ψ_j with $\sum_j |\psi_j| < \infty$. Then for any values $0 < \mu_1 < \dots < \mu_k < \pi$ the variables $I_n(\mu_1), \dots, I_n(\mu_k)$ are asymptotically distributed as independent exponential variables with means $f_X(\mu_1), \dots, f_X(\mu_k)$, respectively.

Proof. First consider the case that $X_t = Z_t$ for every t . Then the spectral density $f_X(\lambda)$ is the function given by $f_Z(\lambda) = \sigma^2/2\pi$, for σ^2 the variance of the white noise sequence. We can write

$$d_Z(\lambda) = \frac{1}{\sqrt{n}} \sum_{t=1}^n Z_t \cos(\lambda t) - i \frac{1}{\sqrt{n}} \sum_{t=1}^n Z_t \sin(\lambda t) =: A_n(\lambda) - iB_n(\lambda).$$

By straightforward calculus we find that, for any $\lambda, \mu \in (0, \pi)$,

$$\begin{aligned}\text{cov}(A_n(\lambda), A_n(\mu)) &= \frac{\sigma^2}{n} \sum_{t=1}^n \cos(\lambda t) \cos(\mu t) \rightarrow \begin{cases} \sigma^2/2 & \text{if } \lambda = \mu, \\ 0 & \text{if } \lambda \neq \mu, \end{cases} \\ \text{cov}(B_n(\lambda), B_n(\mu)) &= \frac{\sigma^2}{n} \sum_{t=1}^n \sin(\lambda t) \sin(\mu t) \rightarrow \begin{cases} \sigma^2/2 & \text{if } \lambda = \mu, \\ 0 & \text{if } \lambda \neq \mu, \end{cases} \\ \text{cov}(A_n(\lambda), B_n(\mu)) &= \frac{\sigma^2}{n} \sum_{t=1}^n \cos(\lambda t) \sin(\mu t) \rightarrow 0.\end{aligned}$$

By the Lindeberg central limit theorem, Theorem 3.16, we now find that the sequence of vectors $(A_n(\lambda), B_n(\lambda), A_n(\mu), B_n(\mu))$ converges in distribution to a vector (G_1, G_2, G_3, G_4) with the $N_4(0, (\sigma^2/2)I)$ distribution. Consequently, by the continuous mapping theorem,

$$(I_n(\lambda), I_n(\mu)) = \frac{1}{2\pi} (A_n^2(\lambda) + B_n^2(\lambda), A_n^2(\mu) + B_n^2(\mu)) \rightsquigarrow \frac{1}{2\pi} (G_1^2 + G_2^2, G_3^2 + G_4^2).$$

The vector on the right is distributed as $\sigma^2/(4\pi)$ times a vector of two independent χ_2^2 variables. Because the chisquare distribution with two degrees of freedom is identical to the standard exponential distribution with parameter $1/2$, this is the same as a vector of two independent exponential variables with means $\sigma^2/(2\pi)$.

This concludes the proof in the special case that $X_t = Z_t$ and for two frequencies λ and μ . The case of k different frequencies μ_1, \dots, μ_k can be treated in exactly the same way, but is notationally more involved.

The spectral density of a general time series of the form $X_t = \sum_j \psi_j Z_{t-j}$ satisfies $f_X(\lambda) = |\psi(\lambda)|^2 f_Z(\lambda)$, for $\psi(\lambda) = \sum \psi_j e^{-ij\lambda}$ the transfer function of the linear filter. We shall prove the theorem by showing that the periodograms $I_{n,X}$ and $I_{n,Z}$ approximately satisfy a similar relation. Indeed, rearranging sums we find

$$d_X(\lambda) = \frac{1}{\sqrt{n}} \sum_{t=1}^n \left(\sum_j \psi_j Z_{t-j} \right) e^{-it\lambda} = \sum_j \psi_j e^{-ij\lambda} \left(\frac{1}{\sqrt{n}} \sum_{s=1-j}^{n-j} Z_s e^{-is\lambda} \right).$$

If we replace the sum $\sum_{s=1-j}^{n-j}$ in the right side by the sum $\sum_{s=1}^n$, then the right side of the display becomes $\psi(\lambda) d_Z(\lambda)$. These two sums differ by $2(|j| \wedge n)$ terms, every of the terms $Z_s e^{-is\lambda}$ having mean zero and variance bounded by σ^2 , and the terms being independent. Thus

$$\mathbb{E} \left| \frac{1}{\sqrt{n}} \sum_{s=1-j}^{n-j} Z_s e^{-is\lambda} - d_Z(\lambda) \right|^2 \leq 2 \frac{|j| \wedge n}{n} \sigma^2.$$

In view of the inequality $\mathbb{E}|X| \leq (\mathbb{E}X^2)^{1/2}$, we can drop the square on the left side if we take a root on the right side. Next combining the two preceding displays and applying the triangle inequality, we find

$$\mathbb{E}|d_X(\lambda) - \psi(\lambda) d_Z(\lambda)| \leq \sum_j |\psi_j| \left(2 \frac{|j| \wedge n}{n} \right)^{1/2} \sigma.$$

The j th term of the series is bounded by $|\psi_j|(2|j|/n)^{1/2}\sigma$ and hence converges to zero as $n \rightarrow \infty$, for every fixed j ; it is also dominated by $|\psi_j|\sqrt{2}\sigma$. Therefore, the right side of preceding display converges to zero as $n \rightarrow \infty$.

By Markov's and Slutsky's lemmas it follows that $d_X(\lambda)$ has the same limit distribution as $\psi(\lambda)d_Z(\lambda)$. Hence, by the continuous mapping theorem, the sequence $I_{n,X}(\lambda)$ has the same limit distribution as $|\psi(\lambda)|^2 I_{n,Z}(\lambda)$. This is true for every fixed λ , but also for finite sets of λ jointly. The proof is finished, because the variables $|\psi(\lambda)|^2 I_{n,Z}(\lambda)$ are asymptotically distributed as independent exponential variables with means $|\psi(\lambda)|^2 f_Z(\lambda)$, by the first part of the proof. ■

A remarkable aspect of the preceding theorem is that the periodogram values $I_n(\lambda)$ at different frequencies are asymptotically independent. This is well visible already for finite values of n in plots of the periodogram, which typically have a wild and peaky appearance. The theorem says that for large n such a plot should be similar to a plot of independent exponentially distributed variables E_λ with means $f_X(\lambda)$ (on the y -axis) versus λ (on the x -axis).

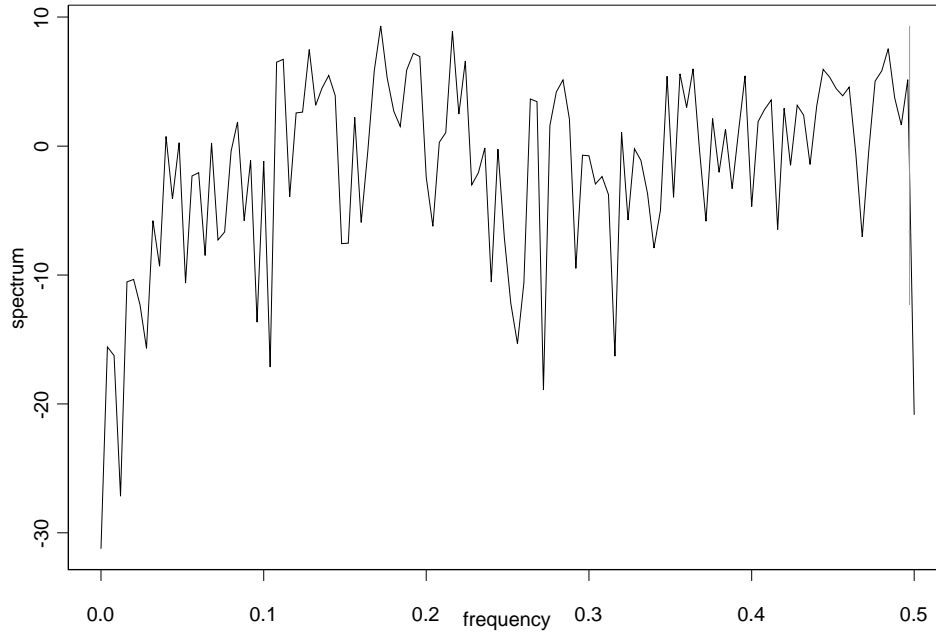

Figure 12.1. Periodogram of a realization of the moving average $X_t = 0.5Z_t + 0.2Z_{t-1} + 0.5Z_{t-2}$ for a Gaussian white noise series. (Vertical scale in decibel, i.e. $^{10}\log$.)

The following theorem shows that we even have independence of the periodogram values at natural frequencies that converge to the same value.

12.5 Theorem. Let $X_t = \sum \psi_j Z_{t-j}$ for an i.i.d. sequence Z_t with finite second moments and coefficients ψ_j with $\sum_j |\psi_j| < \infty$. Let $\lambda_n = (2\pi/n)j_n$ for $j_n \in \mathbb{Z}$ be a sequence of natural frequencies such that $\lambda_n \rightarrow \lambda \in (0, \pi)$. Then for any $k \in \mathbb{Z}$ the variables $I_n(\lambda_n - k2\pi/n), I_n(\lambda_n - (k-1)2\pi/n), \dots, I_n(\lambda_n + k2\pi/n)$ are asymptotically distributed as independent exponential variables with mean $f_X(\lambda)$.

Proof. The second part of the proof of Theorem 12.4 is valid uniformly in λ and hence applies to sequences of frequencies λ_n . For instance, the continuity of $\psi(\lambda)$ and the proof shows that $|d_X(\mu_n) - \psi(\mu_n)d_Z(\mu_n)| \xrightarrow{P} 0$ for any sequence μ_n . It suffices to extend the first part of the proof, which concerns the special case that $X_t = Z_t$.

Here we apply the same method as in the proof of Theorem 12.4. The limits of the covariances are as before, where in the present case we use the fact that we are considering natural frequencies only. For instance,

$$\text{cov}\left(A_n\left(k\frac{2\pi}{n}\right), B_n\left(l\frac{2\pi}{n}\right)\right) = \frac{\sigma^2}{n} \sum_{t=1}^n \cos\left(kt\frac{2\pi}{n}\right) \sin\left(lt\frac{2\pi}{n}\right) = 0,$$

for every integers k, l such that $(k+l)/n$ and $(k-l)/n$ are not contained in \mathbb{Z} .^b An application of the Lindeberg central limit theorem concludes the proof. ■

The sequences of frequencies $\lambda_n + j(2\pi/n)$ considered in the preceding theorem all converge to the same value λ . That Theorem 12.4 remains valid (it does) if we replace the fixed frequencies μ_j in this theorem by sequences $\mu_{j,n} \rightarrow \mu_j$ is not very surprising. More surprising is the asymptotic independence of the periodograms $I_n(\mu_{n,j})$ even if every sequence $\mu_{n,j}$ converges to the same frequency λ . As the proof of the preceding theorem shows, this depends crucially on using natural frequencies $\mu_{n,j}$.

The remarkable independence of the periodogram at frequencies that are very close together is a further explanation of the peaky appearance of the periodogram $I_n(\lambda)$ as a function of λ . It is clear that this function is not a good estimator of the spectral density. However, the independence suggests ways of improving our estimator for $f_X(\lambda)$: the values $I_n(\lambda_n - k2\pi/n), I_n(\lambda_n - (k-1)2\pi/n), \dots, I_n(\lambda_n + k2\pi/n)$ can be viewed as a sample of *independent* estimators of $f_X(\lambda)$, for any k . Rather than one exponentially distributed variable, we therefore have many exponentially distributed variables, all with the same (asymptotic) mean. We exploit this in the next section.

In practice the periodogram may have one or a few extremely high peaks that completely dominate its graph. This indicates an important cyclic component in the time series at those frequencies. Cyclic components of smaller amplitude at other frequencies may be hidden. It is practical wisdom that in such a case a fruitful spectral analysis at other frequencies requires that the peak frequencies are first removed from the signal (by a filter with the appropriate transfer function). We next estimate the spectrum of the new time series and, if desired, transform this back to obtain the spectrum of the original series, using the formula given in Theorem 6.11. Because a spectrum without

^b Actually for all k, l , as a more elaborate argument may show.

high peaks is similar to the uniform spectrum of a white noise series, this procedure is known as *prewhitening* of the data.

12.3 Estimating a Spectral Density

Given $\lambda \in (0, \pi)$ and n , let λ_n be the natural frequency closest to λ . Then $\lambda_n \rightarrow \lambda$ as $n \rightarrow \infty$ and Theorem 12.5 shows that for any $k \in \mathbb{Z}$ the variables $I_n(\lambda_n + j2\pi/n)$ for $j = -k, \dots, k$ are asymptotically distributed as independent exponential variables with mean $f_X(\lambda)$. This suggests to estimate $f_X(\lambda)$ by the average

$$(12.4) \quad \hat{f}_k(\lambda) = \frac{1}{2k+1} \sum_{|j| \leq k} I_n\left(\lambda_n + \frac{2\pi}{n}j\right).$$

As a consequence of Theorem 12.5, the variables $(2k+1)\hat{f}_k(\lambda)$ are asymptotically (as $n \rightarrow \infty$, for fixed k) distributed according the Gamma distribution with shape parameter $2k+1$ and mean $(2k+1)f_X(\lambda)$. This suggests a confidence interval for $f_X(\lambda)$ of the form, with $\chi_{k,\alpha}^2$ the α -quantile of the chisquare distribution with k degrees of freedom,

$$\left(\frac{(4k+2)\hat{f}_k(\lambda)}{\chi_{4k+2,1-\alpha}^2}, \frac{(4k+2)\hat{f}_k(\lambda)}{\chi_{4k+2,\alpha}^2} \right).$$

12.6 EXERCISE. Show that, for every fixed k , this interval is asymptotically of level $1 - 2\alpha$. [Hint: a $\Gamma(m/2, 1/2)$ -distribution is identical to a χ_m^2 -distribution.]

Instead of a simple average we may prefer a weighted average. For given weights W_j such that $\sum_j W_j = 1$, we use

$$(12.5) \quad \hat{f}_k(\lambda) = \sum_j W_j I_n\left(\lambda_n + \frac{2\pi}{n}j\right).$$

This allows to give greater weight to frequencies $\lambda_n + (2\pi/n)j$ that are closer to λ . A disadvantage is that the asymptotic distribution is relatively complicated: it is a weighted sum of independent exponential variables. Because tabulating these types of distributions is complicated, one often approximates them by a scaled chisquare distribution, where the scaling and the degrees of freedom are chosen to match the first two moments: the estimator $c^{-1}\hat{f}_k(\lambda)$ is approximately χ_ν^2 distributed for c and ν solving the equations

$$\begin{aligned} \text{asymptotic mean of } \hat{f}_k(\lambda) &= f_X(\lambda) = c\nu, \\ \text{asymptotic variance of } \hat{f}_k(\lambda) &= \sum_j W_j^2 f_X^2(\lambda) = c^2 2\nu. \end{aligned}$$

This yields c proportional to $f_X(\lambda)$ and ν dependent on $\sum_j W_j^2$ only, $f_X(\lambda)$, and thus confidence intervals based on this approximation can be derived as before. Rather than

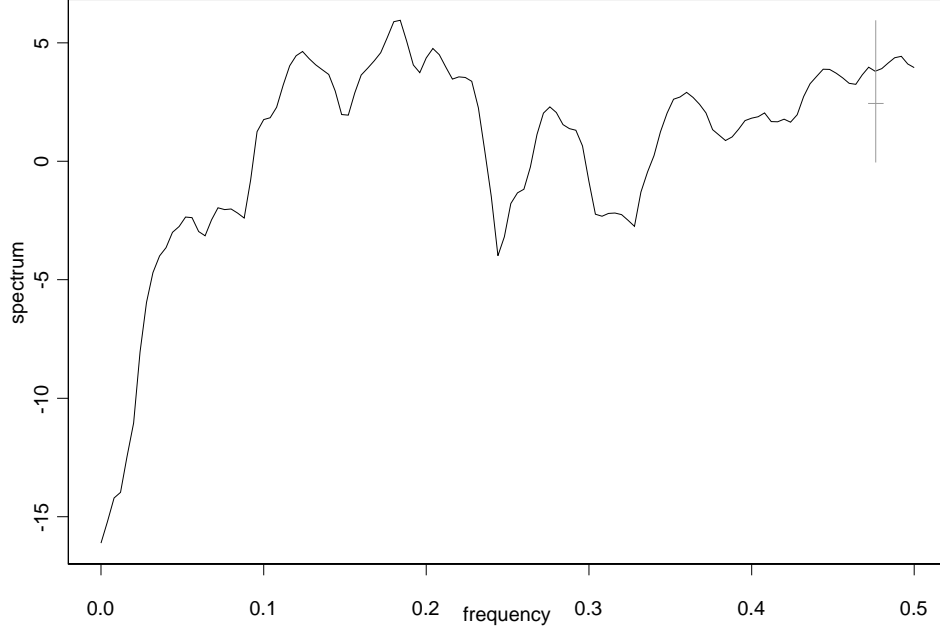

Figure 12.2. Smoothed periodogram of a realization of the moving average $X_t = 0.5Z_t + 0.2Z_{t-1} + 0.5Z_{t-2}$ for a Gaussian white noise series. (Vertical scale in decibel, i.e. $^{10}\log$.)

using the approximation, we could of course determine the desired quantiles by computer simulation.

Because the periodogram is continuous as a function of λ , a discrete average (over natural frequencies) can be closely approximated by a continuous average of the form

$$(12.6) \quad \hat{f}_W(\lambda) = \int W(\omega) I_{n, X - \bar{X}}(\lambda - \omega) d\omega.$$

Here the weight function W is to satisfy $\int W(\omega) d\omega = 1$ and would typically concentrate its mass near zero, so that the average is computed over $I_{n, X - \bar{X}}(\omega)$ for $\omega \approx \lambda$. We use the periodogram of the centered series $X - \bar{X}$, because the average involves nonnatural frequencies. In view of (12.2) this estimator can be written in the form

$$\hat{f}_W(\lambda) = \int W(\omega) \frac{1}{2\pi} \sum_{|h| < n} \hat{\gamma}_n(h) e^{-i(\lambda - \omega)h} d\omega = \frac{1}{2\pi} \sum_{|h| < n} w(h) \hat{\gamma}_n(h) e^{-i\lambda h},$$

where $w(h) = \int e^{i\omega h} W(\omega) d\omega$ are the Fourier coefficients of the weight function. Thus we have arrived at a generalization of the estimator (12.1). If we choose $w(h) = 1$ for $|h| < r$ and $w(h) = 0$ otherwise, then the preceding display exactly gives (12.1). The more

general form can be motivated by the same reasoning: the role of the coefficients $w(h)$ is to diminish the influence of the relatively unreliable estimators $\hat{\gamma}_n(h)$ (for $h \approx n$) when plugging in these sample estimators for the true auto-covariances in the expression for the spectral density. Thus, the weights $w(h)$ are typically chosen to decrease in absolute value from $|w(0)| = 1$ to $|w(n)| = 0$ if h increases from 0 to n .

The function W is known as the *spectral window*; its Fourier coefficients $w(h)$ are known as the *lag window*, *tapering function* or *convergence factors*. The last name comes from Fourier analysis, where convergence factors were introduced to improve the approximation properties of a Fourier series: it was noted that for suitably chosen weights $w(h)$ the partial sums $\sum_{|h| < n} w(h) \gamma_X(h) e^{-ih\lambda}$ could be much closer to the full series $\sum_h \gamma_X(h) e^{-ih\lambda}$ than the same partial sums with $w \equiv 1$. In our statistical context this is even more so the case, because we introduce additional approximation error by replacing the coefficients $\gamma_X(h)$ by the estimators $\hat{\gamma}_n(h)$.

12.7 Example (Dirichlet kernel, uniform tapering). The tapering function

$$w(h) = \begin{cases} 1 & \text{if } |h| \leq r, \\ 0 & \text{if } |h| > r, \end{cases}$$

corresponds to the Dirichlet kernel

$$W(\lambda) = \frac{1}{2\pi} \sum_{|h| \leq r} e^{-ih\lambda} = \frac{1}{2\pi} \frac{\sin(r + \frac{1}{2})\lambda}{\sin \frac{1}{2}\lambda}.$$

Therefore, the estimator (12.1) should be compared to the estimators (12.5) and (12.6) with weights W_j chosen according to the Dirichlet kernel. \square

12.8 Example (Uniform kernel). The uniform kernel

$$W(\lambda) = \begin{cases} r/(2\pi) & \text{if } |\lambda| \leq \pi/r, \\ 0 & \text{if } |\lambda| > \pi/r, \end{cases}$$

corresponds to the weight function $w(h) = r \sin(\pi h/r)/(\pi h)$. These choices of spectral and lag windows correspond to the estimator (12.4). \square

All estimators for the spectral density considered so far can be viewed as *smoothed periodograms*: the value $\hat{f}(\lambda)$ of the estimator at λ is an average or weighted average of values $I_n(\mu)$ for μ in a neighbourhood of λ . Thus “irregularities” in the periodogram are “smoothed out”. The amount of smoothing is crucial for the accuracy of the estimators. This amount, called the *bandwidth*, is determined by the parameter k in (12.4), the weights W_j in (12.5), the kernel W in (12.6), and, more hidden, by the parameter r in (12.1). For instance, a large value of k in (12.4) or a kernel W with a large variance in (12.6) result in a large amount of smoothing (large bandwidth). *Oversmoothing*, choosing a bandwidth that is too large, results in spectral estimators that are too flat and therefore inaccurate, whereas *undersmoothing*, choosing too small a bandwidth, yields

spectral estimators that share the bad properties of the periodogram. In practice an “optimal” bandwidth is often determined by plotting the spectral estimators for a number of different bandwidths and next choosing the one that looks “reasonable”. An alternative is to use one of several methods of “data-driven” choices of bandwidths, such as cross validation or penalization. We omit a discussion.

Theoretical analysis of the choice of the bandwidth is almost exclusively asymptotical in nature. Given a number of observations tending to infinity, the “optimal” bandwidth decreases to zero. A main concern of an asymptotic analysis is to determine the rate of decrease. The key concept is the *bias-variance trade-off*. Because the periodogram is more or less unbiased, little smoothing gives an estimator with small bias. However, as we have seen, the estimator will have a large variance. Oversmoothing has the opposite effects: it cuts variance by including more (independent) information, but creates bias unless the spectral density is constant in an interval. Because accurate estimation requires that both bias and variance are small, we need an intermediate value of the bandwidth.

We shall quantify this bias-variance trade-off for estimators of the type (12.1), where we consider r as the bandwidth parameter. As our objective we take to minimize the mean integrated square error

$$(12.7) \quad 2\pi \mathbb{E} \int_{-\pi}^{\pi} |\hat{f}_{n,r}(\lambda) - f_X(\lambda)|^2 d\lambda.$$

The integrated square error is a global measure of the discrepancy between $\hat{f}_{n,r}$ and f_X . Because we are interested in f_X as a function, it is more relevant than the distance $|\hat{f}_{n,r}(\lambda) - f_X(\lambda)|$ for any fixed λ .

We shall use Parseval’s identity, which says that the space $L_2(-\pi, \pi]$ is isometric to the space ℓ_2 .

12.9 Lemma (Parseval’s identity). *Let $f: (-\pi, \pi] \rightarrow \mathbb{C}$ be a measurable function such that $\int |f|^2(\lambda) d\lambda < \infty$. Then its Fourier coefficients $f_j = \int_{-\pi}^{\pi} e^{ij\lambda} f(\lambda) d\lambda$ satisfy*

$$\int_{-\pi}^{\pi} |f(\lambda)|^2 d\lambda = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} |f_j|^2.$$

12.10 EXERCISE. Prove this identity. Also show that for a pair of square-integrable, measurable functions $f, g: (-\pi, \pi] \rightarrow \mathbb{C}$ we have $\int f(\lambda) \bar{g}(\lambda) d\lambda = \sum_j f_j \bar{g}_j$.

The function $\hat{f}_{n,r} - f_X$ possesses the Fourier coefficients $\hat{\gamma}_n(h) - \gamma_X(h)$ for $|h| < r$ and $-\gamma_X(h)$ for $|h| \geq r$. Thus, Parseval’s identity yields that the mean integrated square error (12.7) is equal to

$$\mathbb{E} \sum_{|h| < r} |\hat{\gamma}_n(h) - \gamma_X(h)|^2 + \sum_{|h| \geq r} |\gamma_X(h)|^2$$

In a rough sense the two terms in this formula are the “variance” and the square “bias” term. A large value of r clearly decreases the second, square bias term, but increases the

first, variance term. This variance term can itself be split into a bias and variance term and we can reexpress the mean integrated square error as

$$\sum_{|h|<r} \text{var } \hat{\gamma}_n(h) + \sum_{|h|<r} |\mathbb{E} \hat{\gamma}_n(h) - \gamma_X(h)|^2 + \sum_{|h|\geq r} |\gamma_X(h)|^2.$$

Assume for simplicity that $\mathbb{E}X_t = 0$ and that $X_t = \sum_j \psi_j Z_{t-j}$ for a summable sequence (ψ_j) and i.i.d. sequence Z_t with finite fourth moments. Furthermore, assume that we use the estimator $\hat{\gamma}_n(h) = n^{-1} \sum_{t=1}^{n-h} X_{t+h} X_t$ rather than the true sample auto-covariance function. (The results for the general case are similar, but the calculations will be more involved. Note that the difference between the present estimator and the usual one is approximately \bar{X}^2 and $\sum_{|h|<r} \mathbb{E}(\bar{X})^4 = O(r/n^2)$, under appropriate moment conditions. This is negligible in the following.) Then the calculations in Chapter 5 show that the preceding display is equal to

$$\begin{aligned} & \sum_{|h|<r} \frac{1}{n^2} \sum_{|g|<n-|h|} (n-|h|-|g|) \left[\kappa_4 \sigma^4 \sum_i \psi_i \psi_{i+h} \psi_{i+g} \psi_{i+g+h} + \gamma_X^2(g) \right. \\ & \quad \left. + \gamma_X(g+h) \gamma_X(g-h) \right] + \sum_{|h|<r} \left(\frac{|h|}{n} \gamma_X(h) \right)^2 + \sum_{|h|\geq r} \gamma_X^2(h) \\ & \leq \frac{|\kappa_4| \sigma^4}{n} \sum_h \sum_g \sum_i |\psi_i \psi_{i+h} \psi_{i+g} \psi_{i+g+h}| + \frac{2r+1}{n} \sum_g \gamma_X^2(g) \\ & \quad + \frac{1}{n} \sum_h \sum_g |\gamma_X(g+h) \gamma_X(g-h)| + \frac{r^2}{n^2} \sum_h \gamma_X^2(h) + \sum_{|h|\geq r} \gamma_X^2(h). \end{aligned}$$

To ensure that the second and last terms on the right converge to zero as $n \rightarrow \infty$ we must choose $r = r_n$ such that $r_n/n \rightarrow 0$ and $r_n \rightarrow \infty$, respectively. The first and third term are of the order $O(1/n)$, and the fourth term is of the order $O(r_n^2/n^2)$. Under the requirements $r_n \rightarrow \infty$ and $r_n/n \rightarrow 0$ these terms are dominated by the other terms, and the whole expression is of the order

$$\frac{r_n}{n} + \sum_{|h|\geq r_n} \gamma_X^2(h).$$

A first conclusion is that the sequence of estimators \hat{f}_{n,r_n} is asymptotically consistent for estimating f_X relative to the L_2 -distance whenever $r_n \rightarrow \infty$ and $r_n/n \rightarrow 0$. A wide range of sequences r_n satisfy these constraints. For an optimal choice we must make assumptions regarding the rate at which the bias term $\sum_{|h|\geq r} \gamma_X^2(h)$ converges to zero as $r \rightarrow \infty$. For any constant m we have that

$$\frac{r_n}{n} + \sum_{|h|\geq r_n} \gamma_X(h)^2 \leq \frac{r_n}{n} + \frac{1}{r_n^{2m}} \sum_h \gamma_X^2(h) h^{2m}.$$

Suppose that the series on the far right converges; this means roughly that the auto-covariances $\gamma_X(h)$ decrease faster than $|h|^{-m-1/2}$ as $|h| \rightarrow \infty$. Then we can make a

bias-variance trade-off by balancing the terms r_n/n and $1/r_n^{2m}$. These terms are of equal order for $r_n \asymp n^{1/(2m+1)}$; for this choice of r_n we find that

$$\mathbb{E} \int_{-\pi}^{\pi} |\hat{f}_{n,r_n}(\lambda) - f_X(\lambda)|^2 d\lambda = O\left(\left(\frac{1}{n}\right)^{2m/(2m+1)}\right).$$

Large values of m yield the fastest rates of convergence. The rate $n^{-m/(2m+1)}$ is always slower than $n^{-1/2}$, the rate obtained when using parametric spectral estimators, but approaches this rate as $m \rightarrow \infty$.

Unfortunately, in practice we do not know $\gamma_X(h)$ and therefore cannot check whether the preceding derivation is valid. So-called *cross-validation* techniques may be used to determine a suitable constant m from the data.

The condition that $\sum_h \gamma_X^2(h)h^{2m} < \infty$ can be interpreted in terms of the smoothness of the spectral density. It can be shown (see Exercise 12.11) that the Fourier coefficients of the m th derivative $f_X^{(m)}$ of f_X are equal to $\gamma_X(h)(-ih)^m$. Consequently, by Parseval's identity

$$\sum_h \gamma_X^2(h)h^{2m} = \int_{-\pi}^{\pi} f_X^{(m)}(\lambda)^2 d\lambda.$$

Thus the left side is finite if and only if the m th derivative of f_X exists and is square-integrable. Thus for time series with such an m -smooth spectral density, one can estimate the spectral density with an integrated square error of order $O(n^{-2m/(2m+1)})$. This rate is uniform over the set of all time series with spectral densities such that $\int f_X^{(m)}(\lambda)^2 d\lambda$ is uniformly bounded, i.e. balls in the *Sobolev space* of order m .

12.11 EXERCISE. Show that the Fourier coefficients $\int_{-\pi}^{\pi} e^{ij\lambda} f'(\lambda) d\lambda$ of the derivative of a continuously differentiable function $f: [-\pi, \pi] \rightarrow \mathbb{R}$ with $f(-\pi) = f(\pi)$, are equal to $-ijf_j$, for f_j the Fourier coefficients of f . [Hint: apply partial integration.]

This conclusion is similar to the conclusion in the problem of estimating a density given a random sample from this density, where also m -smooth densities can be estimated with an integrated square error of order $O(n^{-2m/(2m+1)})$. The smoothing methods discussed previously (the estimator (12.6) in particular) are also related to the method of kernel smoothing for density estimation. It is interesting that historically the method of smoothing was first applied to the problem of estimating a spectral density. Here kernel smoothing of the periodogram was a natural extension of taking simple averages as in (12.4), which itself is motivated by the independence property of the periodogram. The method of kernel smoothing for the problem of density estimation based on a random sample from this density was invented later, even though this problem by itself appears to be simpler.

* 12.4 Estimating a Spectral Distribution

In the preceding section it is seen that nonparametric estimation of a spectral density requires smoothing and yields rates of convergence $n^{-\alpha}$ for values of $\alpha < 1/2$. In contrast, a spectral distribution function can be estimated at the “usual” rate of convergence $n^{-1/2}$ and natural estimators are asymptotically normally distributed. We assume X_t is a stationary time series with spectral density f_X .

The spectral distribution function $F_X(\lambda_0) = \int_{-\pi}^{\lambda_0} f_X(\lambda) d\lambda$ can be written in the form

$$\int_{-\pi}^{\pi} a(\lambda) f_X(\lambda) d\lambda$$

for a the indicator function of the interval $(-\pi, \lambda_0]$. We shall consider estimation of a general functional of this type by the estimator

$$I_n(a) := \int_{-\pi}^{\pi} a(\lambda) I_n(\lambda) d\lambda.$$

12.12 Theorem. Suppose that $X_t = \sum_j \psi_j Z_{t-j}$ for an i.i.d. sequence Z_t with finite fourth cumulant κ_4 and constants ψ_j such that $\sum_j |\psi_j| < \infty$. Moreover, assume that $\sum_h |h| \gamma_X^2(h) < \infty$. Then, for any symmetric function a such that $\int_{-\pi}^{\pi} a^2(\lambda) d\lambda < \infty$,

$$\sqrt{n} \left(I_n(a) - \int a f_X d\lambda \right) \rightsquigarrow N \left(0, \kappa_4 \left(\int a f_X d\lambda \right)^2 + 4\pi \int a^2 f_X^2 d\lambda \right).$$

Proof. We can expand $a(\lambda)$ in its Fourier series $a(\lambda) = \sum_j a_j e^{-ij\lambda}$ (say). By Parseval’s identity

$$\int a f_X d\lambda = \sum_h \gamma_X(h) a_h.$$

Similarly, by (12.2) and Parseval’s identity

$$I_n(a) = \int a I_n d\lambda = \sum_{|h| < n} \hat{\gamma}_n^*(h) a_h.$$

First suppose that $a_h = 0$ for $|h| > m$ and some m . Then $\int a I_n d\lambda$ is a linear combination of $(\hat{\gamma}_n(0), \dots, \hat{\gamma}_n(m))$. By Theorem 5.8, as $n \rightarrow \infty$,

$$\sqrt{n} \left(\sum_h \hat{\gamma}_n(h) a_h - \sum_h \gamma_X(h) a_h \right) \rightsquigarrow \sum_h a_h Z_h,$$

where $(Z_{-m}, \dots, Z_0, Z_1, \dots, Z_m)$ is a mean zero normally distributed random vector such that (Z_0, \dots, Z_m) has covariance matrix V as in Theorem 5.8 and $Z_{-h} = Z_h$ for every

h . Thus $\sum_h a_h Z_h$ is normally distributed with mean zero and variance

$$\begin{aligned}
 \sum_g \sum_h V_{g,h} a_g a_h &= \kappa_4 \left(\sum_g a_g \gamma_X(g) \right)^2 + \sum_g \sum_h \left(\sum_k \gamma_X(k+h) \gamma_X(k+g) \right. \\
 (12.8) \quad &\quad \left. + \sum_k \gamma_X(k+h) \gamma_X(k-g) \right) a_g a_h \\
 &= \kappa_4 \left(\int a f_X d\lambda \right)^2 + 4\pi \int a^2 f_X^2 d\lambda.
 \end{aligned}$$

The last equality follows after a short calculation, using that $a_h = a_{-h}$. (Note that we have used the expression for $V_{g,h}$ given in Theorem 5.8 also for negative g or h , which is correct, because both $\text{cov}(Z_g, Z_h)$ and the expression in Theorem 5.8 remain the same if g or h is replaced by $-g$ or $-h$.)

This concludes the proof in the case that $a_h = 0$ for $|h| > m$, for some m . The general case is treated with the help of Lemma 3.10. Set $a_m = \sum_{|j| \leq m} a_j e^{-i\lambda j}$ and apply the preceding argument to $X_{n,m} := \sqrt{n} \int a_m (I_n - f_X) d\lambda$ to see that $X_{n,m} \rightsquigarrow N(0, \sigma_m^2)$ as $n \rightarrow \infty$, for every fixed m . The asymptotic variance σ_m^2 is the expression given in the theorem with a_m instead of a . If $m \rightarrow \infty$, then σ_m^2 converges to the expression in the theorem, by the dominated convergence theorem, because a is squared-integrable and f_X is uniformly bounded. Therefore, by Lemma 3.10 it suffices to show that for every $m_n \rightarrow \infty$

$$(12.9) \quad \sqrt{n} \int (a - a_{m_n})(I_n - f_X) d\lambda \xrightarrow{P} 0.$$

Set $b = a - a_{m_n}$. The variance of the random variable in (12.9) is the same as the variance of $\int (a - a_{m_n}) I_n d\lambda$, and can be computed as, in view of Parseval's identity,

$$\begin{aligned}
 \text{var} \left(\frac{\sqrt{n}}{2\pi} \sum_{|h| < n} \hat{\gamma}_n(h) b_h \right) &= \frac{n}{4\pi^2} \sum_{|g| < n} \sum_{|h| < n} \text{cov}(\hat{\gamma}_n(g), \hat{\gamma}_n(h)) b_g b_h \\
 &= \frac{n}{4\pi^2} \sum_{|g| < n} \sum_{|h| < n} \frac{1}{n^2} \sum_{s=1}^{n-|g|} \sum_{t=1}^{n-|h|} \text{cov}(X_{s+g} X_s, X_{t+h} X_t) b_g b_h.
 \end{aligned}$$

Using the same approach as in Section 5.2, we can rewrite this as

$$\begin{aligned}
 \frac{1}{4\pi^2 n} \sum_{|g| < n} \sum_{|h| < n} \sum_{s=1}^{n-|g|} \sum_{t=1}^{n-|h|} &\left(\kappa_4 \sigma^4 \sum_i \psi_{i+g} \psi_i \psi_{t-s+h+i} \psi_{t-s+i} \right. \\
 &\left. + \gamma_X(t-s+h-g) \gamma_X(t-s) + \gamma_X(t-s-g) \gamma_X(t-s+h) \right) b_g b_h.
 \end{aligned}$$

The absolute value of this expression can be bounded above by

$$\begin{aligned} & \frac{1}{4\pi^2} \sum_g \sum_h \sum_k \left(\sum_i |\psi_{i+g} \psi_i \psi_{k+h+i} \psi_{k+i}| |\kappa_4| \sigma^4 + |\gamma_X(k+h-g) \gamma_X(k)| \right. \\ & \quad \left. + |\gamma_X(k-g) \gamma_X(k+h)| \right) |b_g b_h| \\ &= \frac{1}{4\pi^2} \left(|k_4| \left(\int \underline{b} \underline{f}_{\equiv X} d\lambda \right)^2 + 4\pi \underline{b}^2 \int \underline{f}_X^2 d\lambda \right), \end{aligned}$$

by the same calculation as in (12.8), where we define

$$\underline{b} = \sum_h |b_h| e^{-i\lambda h}, \quad \underline{f}_{\equiv X}(\lambda) = \sum_h \sum_i |\psi_i \psi_{i+h}| \sigma^2 e^{-i\lambda h}, \quad \underline{f}_X(\lambda) = \sum_h |\gamma_X(h)| e^{-i\lambda h}.$$

Under our assumptions \underline{f}_X and $\underline{f}_{\equiv X}$ are bounded functions. It follows that $\text{var} \int b_n I_n d\lambda \rightarrow 0$ if $\int \underline{b}_n^2 d\lambda \rightarrow 0$. This is true in particular for $b_n = a - a_{m_n}$.

Next the mean of the left side of (12.9) can be computed as

$$\begin{aligned} \sqrt{n} \left(\sum_{|h| < n} E \hat{\gamma}_n(h) b_h - \int b f_X d\lambda \right) &= \sqrt{n} \left(\sum_{|h| < n} \frac{n - |h|}{n} \gamma_X(h) b_h - \sum_h \gamma_X(h) b_h \right) \\ &= - \sum_h \frac{n \wedge |h|}{\sqrt{n}} \gamma_X(h) b_h. \end{aligned}$$

By the Cauchy-Schwarz inequality this is bounded in absolute value by the square root of

$$\sum_h |b_h|^2 \sum_h \frac{(n \wedge |h|)^2}{n} \gamma_X^2(h) \leq \sum_h |b_h|^2 \sum_h |h| \gamma_X^2(h).$$

Under our assumptions this converges to zero as $\int \underline{b}^2 d\lambda \rightarrow 0$. ■

The preceding theorem is restricted to symmetric functions a , but can easily be extended to general functions, because by the symmetry of the spectral density

$$\int a(\lambda) f_X(\lambda) d\lambda = \int \frac{a(\lambda) + a(-\lambda)}{2} f_X(\lambda) d\lambda.$$

12.13 EXERCISE. Show that for a possibly nonsymmetric function a the theorem is valid, but with asymptotic variance

$$\kappa_4 \left(\int a f_X d\lambda \right)^2 + 2\pi \int_{-\pi}^{\pi} a^2 f_X^2 d\lambda + 2\pi \int_{-\pi}^{\pi} a(\lambda) a(-\lambda) f_X^2(\lambda) d\lambda.$$

12.14 Example. To obtain the limit distribution of the estimator for the spectral distribution function at the point $\lambda_0 \in [0, \pi]$, we apply the theorem with the symmetric function $a = (1_{(-\pi, \lambda_0]} + 1_{(-\lambda_0, \pi]})$. The asymptotic variance is equal to $\kappa_4 F_X(\lambda_0)^2 + 4\pi \int_{\lambda_0}^{\lambda_0} f_X^2 d\lambda + 2\pi \int_{\lambda_0}^{\pi} f_X^2 d\lambda$ for $\lambda_0 \in [0, \pi]$. □

12.15 Example. The choice $a(\lambda) = \cos(h\lambda)$ yields the estimator (for $0 \leq h < n$)

$$\int \cos(h\lambda) I_n(\lambda) d\lambda = \operatorname{Re} \int e^{ih\lambda} I_n(\lambda) d\lambda = \frac{1}{n} \sum_{t=1}^{n-h} X_{t+h} X_t$$

of the auto-covariance function $\gamma_X(h)$ in the case that $\operatorname{E}X_t = 0$. Thus the preceding theorem contains Theorem 5.8 as a special case. The present theorem shows how the asymptotic covariance of the sample auto-covariance function can be expressed in the spectral density. \square

12.16 EXERCISE. Show that the sequence of bivariate random vectors $\sqrt{n}(\int a(I_n - f_X) d\lambda, \int b(I_n - f_X) d\lambda)$ converges in distribution to a bivariate Gaussian vector (G_a, G_b) with mean zero and $\operatorname{E}G_a G_b = \kappa_4 \int a f_X d\lambda \int b f_X d\lambda + 4\pi \int a b f_X^2 d\lambda$.

12.17 EXERCISE. Plot the periodogram of a white noise series of length 200. Does this look like a plot of 200 independent exponential variables?

12.18 EXERCISE. Estimate the spectral density of the simulated time series given in the file `~sda/Cursusdata/sim2` by a smoothed periodogram. Compare this to the estimate obtained assuming that `sim2` is an AR(3) series.

12.19 EXERCISE. Estimate the spectral density of the Wölfer sunspot numbers (the object `sunspots` in Splus) by

- (i) a smoothed periodogram;
- (ii) the spectral density of an appropriate AR-model.

Note: the mean is nonzero.

13

Maximum Likelihood

The method of maximum likelihood is one of the unifying principles of statistics, and applies equally well to replicated experiments as to time series. Given observations X_1, \dots, X_n with a joint probability density $(x_1, \dots, x_n) \mapsto p_{n,\theta}(x_1, \dots, x_n)$ that depends on a parameter θ , the *likelihood function* is the stochastic process

$$\theta \mapsto p_{n,\theta}(X_1, \dots, X_n).$$

The *maximum likelihood estimator* for θ , if it exists, is the value of θ that maximizes the likelihood function.

The likelihood function corresponding to i.i.d. observations X_1, \dots, X_n is the product of the likelihood functions of the individual observations, which makes likelihood inference relatively easy in this case. For time series models the likelihood function may be a more complicated function of the observations and the parameter. This complicates the practical implementation of likelihood inference. It also makes its theoretical analysis more involved, although in “most” situations the final results are not that different from the more familiar i.i.d. case. In particular, maximum likelihood estimators of “smooth” finite-dimensional parameters are typically \sqrt{n} -consistent and, after centering at the true parameter and scaling, possess a normal limit distribution, with mean zero and covariance the inverse of the Fisher information matrix.

In this chapter we study the maximum likelihood estimator, and some approximations. We also consider the effect of *model misspecification*: using the likelihood for a model that does not contain the true distribution of the data. Such misspecification of the model may be unintended, but also be deliberate. For instance, the likelihood under the assumption that X_1, \dots, X_n are part of a stationary Gaussian time series X_t is popular for inference, even if one may not believe that the time series is Gaussian. The corresponding maximum likelihood estimator is closely related to the least squares estimators and turns out to perform well also for a wide range of non-Gaussian time series. Another example is to postulate that the innovations in a GARCH model are Gaussian. The resulting estimators again work well also for non-Gaussian innovations.

A misspecified likelihood is also referred to as a *quasi likelihood* and the resulting

estimators as *quasi likelihood estimators*. Alternatively, a misspecified maximum likelihood estimator falls in the class of *M-estimators*, which are defined as the maximizers of a given stochastic process (a *contrast function*). We prefer *M-estimator* over quasi-likelihood estimator. Yet another term, which sometimes refers to the same, is *pseudo likelihood*. In our heuristic discussion of the asymptotic properties of maximum likelihood estimators we use this for a certain process that is close to the likelihood, but has a simpler structure.

13.1 General Likelihood

A convenient representation of a likelihood is obtained by repeated conditioning. To alleviate the notation we abuse notation by writing $p(y|x)$ for a conditional density of a variable Y given that another variable X takes the value x , and denote the marginal density of X by $p(x)$. Thus the argument(s) of the function must reveal its identity. In this notation the likelihood corresponding to the observations X_1, \dots, X_n is $p_\theta(X_1, \dots, X_n)$, and it can be decomposed as

$$(13.1) \quad p_\theta(X_1, \dots, X_n) = p_\theta(X_1)p_\theta(X_2|X_1) \cdots p_\theta(X_n|X_{n-1}, \dots, X_1).$$

Clearly we must select appropriate versions of the (conditional) densities, but we shall not worry about technical details in this section.

The decomposition resembles the factorization of the likelihood of an i.i.d. sample of observations, but an important difference is that the n terms on the right may all be of a different form. Even if the time series X_t is strictly stationary, each further term entails conditioning on a bigger past and hence is potentially of a different character than the earlier terms. However, in many examples the “present” X_t is nearly independent of the “distant past” ($X_s: s \ll t$) given the “near past” ($X_s: s < t, s \approx t$). Then the likelihood does not change much if the conditioning in each term is limited to a fixed number of variables in the past, and most of the terms of the product will take almost a common form. Alternatively, we may augment the conditioning in each term to include the full “infinite past”, yielding the *pseudo likelihood*

$$(13.2) \quad \theta \mapsto p_\theta(X_1|X_0, X_{-1}, \dots)p_\theta(X_2|X_1, X_0, \dots) \times \cdots \times p_\theta(X_n|X_{n-1}, X_{n-2}, \dots).$$

If the time series X_t is strictly stationary, then the t th term $p_\theta(X_t|X_{t-1}, X_{t-2}, \dots)$ in this product is a fixed measurable function, independent of t , applied to the vector (X_t, X_{t-1}, \dots) . In particular, the terms of the product form a strictly stationary time series, which will be ergodic if the original time series X_t is ergodic. This is almost as good as the i.i.d. terms obtained in the case of an i.i.d. time series.

The pseudo likelihood (13.2) cannot be used in practice, because the “negative” variables X_0, X_{-1}, \dots are not observed. However, the preceding discussion suggests that the *maximum pseudo likelihood estimator*, defined as the maximizer of the pseudo likelihood, may behave the same as the true maximum likelihood estimator. Moreover, if it is true that the past observations X_0, X_{-1}, \dots do not play an important role in defining

the pseudo likelihood, then we could also replace them by arbitrary values, for instance zero, and hence obtain an observable criterion function.

13.1 Example (Markov time series). If the time series X_t is Markov, then the conditioning in each term $p_\theta(X_t | X_{t-1}, \dots, X_1)$ or $p_\theta(X_t | X_{t-1}, X_{t-2}, \dots)$ can be restricted to the single variable X_{t-1} . In this case the likelihood and the pseudo likelihood differ only in their first terms, which are $p_\theta(X_1)$ and $p_\theta(X_1 | X_0)$, respectively. This difference should be negligible if n is large.

Similarly, if the time series is *Markov of order p* , i.e. $p(X_t | X_{t-1}, X_{t-2}, \dots)$ depends only on $X_t, X_{t-1}, \dots, X_{t-p}$, then the two likelihoods differ only in p terms. This should be negligible if n is large relative to p . \square

13.2 Example (Autoregression). A causal auto-regressive time series defined relative to an i.i.d. white noise series is an example of a p th order Markov series. Maximum likelihood estimators for auto-regressive processes are commonly defined by using the pseudo likelihood with X_0, \dots, X_{-p+1} set equal to zero. Alternatively, we simply drop the first p terms of the likelihood, and work with the approximate likelihood

$$(\sigma, \phi_1, \dots, \phi_p) \mapsto \prod_{t=p+1}^n p_{Z,\sigma}(X_t - \phi_1 X_{t-1} - \dots - \phi_p X_{t-p}),$$

for $p_{Z,\sigma}$ the density of the innovations. This can also be considered a *conditional likelihood* given the observations X_1, \dots, X_p . The difference of this likelihood with the true likelihood is precisely the marginal density of the vector (X_1, \dots, X_p) , which can be complicated in general, but should have a noticeable effect on the maximum likelihood estimator only if p is large relative to n . \square

13.3 Example (GARCH). A strictly stationary GARCH process X_t relative to an i.i.d. series Z_t can be written as $X_t = \sigma_t Z_t$, for $\sigma_t^2 = E(X_t^2 | \mathcal{F}_{t-1})$ and \mathcal{F}_t the filtration generated by X_t, X_{t-1}, \dots . From Theorem 9.13 it is known that the filtration \mathcal{F}_t is also the natural filtration of the process Z_t and hence the variable Z_t is independent of σ_t , as this is measurable relative to \mathcal{F}_{t-1} . Thus given X_{t-1}, X_{t-2}, \dots the variable $X_t = \sigma_t Z_t$ is obtained by first calculating σ_t from X_{t-1}, X_{t-2}, \dots and next multiplying σ_t by an independent variable Z_t . The conditional distribution of X_t given X_{t-1}, X_{t-2}, \dots is the distribution of Z_t scaled by σ_t . If p_Z is the marginal density of the variables Z_t , then the pseudo likelihood (13.2) takes the form

$$(13.3) \quad \prod_{t=1}^n \frac{1}{\sigma_t} p_Z\left(\frac{X_t}{\sigma_t}\right).$$

The parameters $\alpha, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q$ are hidden in the process σ_t , through the GARCH relation (9.1). Formula (13.3) is not the true likelihood, because it depends on the unobservable variables X_0, X_{-1}, \dots through the σ_t .

For an ARCH(q) process the conditional variances σ_t^2 depend only on the variables X_{t-1}, \dots, X_{t-q} , in the simple form

$$\sigma_t^2 = \alpha + \theta_1 X_{t-1}^2 + \dots + \theta_q X_{t-q}^2.$$

In this case the true likelihood and the pseudolikelihood differ only in the first q of the n terms. This difference should be negligible. For practical purposes, if n is large relative to q , we could either drop those first q terms, giving a conditional likelihood, or act as if the unobserved variables X_0^2, \dots, X_{-q+1}^2 are zero.

For general GARCH processes the difference between the likelihoods is more substantial, because the conditional variance σ_t^2 depends on $X_{t-1}^2, \dots, X_{t-q}^2$ as well as on the previous σ_s^2 , causing a dependence on the full past X_s^2 with $s < t$ of the process of squares. However, the dependence of σ_t^2 on lagged variables X_s^2 decreases exponentially fast as $s \rightarrow \infty$. This suggests that we might again use the pseudo likelihood with the unobserved variables X_s^2 replaced by zero.

That the variables X_s^2 with $s \leq 0$ do not play an important role in the definition of the (pseudo) likelihood is also suggested by Theorem 9.17, which shows that a GARCH series defined from arbitrary starting values converges to (strict) stationarity as t grows to infinity (provided that a strictly stationary GARCH process exists). (It is *suggested* only, as the stability assertion of Theorem 9.17 is about the time series itself and not about its likelihood function.)

A practical implementation is to define $\sigma_0^2, \dots, \sigma_{-p+1}^2$ and X_0^2, \dots, X_{-q+1}^2 to be zero, and next compute $\sigma_1^2, \sigma_2^2, \dots$ recursively, using the GARCH relation (9.1) and the observed values X_1, \dots, X_n . By Theorem 9.17 these zero starting values cannot be the true values of the series if the series is strictly stationary, but any other initialization should yield approximately the same likelihood. Given $\sigma_1^2, \sigma_2^2, \dots, \sigma_n^2$ and X_1, \dots, X_n we can use (13.3) as a contrast function. \square

13.2 Asymptotics under a Correct Model

In this section we consider the asymptotic behaviour of the maximum likelihood estimator under the assumption that the observations are sampled according to one of the distributions used to form the likelihood. We denote the parameter of latter distribution by θ_0 .

We adopt the working hypothesis that the maximum likelihood estimators have the same asymptotic properties as the corresponding maximum pseudo likelihood estimators. Furthermore, we assume that the time series X_t is strictly stationary and ergodic. These conditions are certainly too stringent, but they simplify the arguments. The conclusions typically apply to any time series that “approaches stationarity” as $t \rightarrow \infty$ and for which averages converge to constants.

13.2.1 Consistency

Abbreviate X_t, X_{t-1}, \dots to \vec{X}_t . The maximum pseudo likelihood estimator maximizes the function

$$(13.4) \quad \theta \mapsto M_n(\theta) = \frac{1}{n} \sum_{t=1}^n \log p_\theta(X_t | \vec{X}_{t-1}).$$

If the variables $\log p_\theta(X_t | \vec{X}_{t-1})$ are integrable, as we assume, then, by the ergodic theorem, Theorem 7.4, the averages $M_n(\theta)$ converge to their expectation

$$(13.5) \quad M(\theta) = E_{\theta_0} \log p_\theta(X_1 | \vec{X}_0).$$

The expectation is taken under the “true” parameter θ_0 governing the distribution of the time series X_t . The difference of the expected values $M(\theta_0)$ and $M(\theta)$ can be written as, for μ the dominating measure of the conditional densities $p_\theta(\cdot | \vec{X}_0)$,

$$M(\theta_0) - M(\theta) = E_{\theta_0} \int \left(\log \frac{p_{\theta_0}(x_1 | \vec{X}_0)}{p_\theta(x_1 | \vec{X}_0)} \right) p_{\theta_0}(x_1 | \vec{X}_0) d\mu(x_1).$$

The integral inside the expectation is the Kullback-Leibler divergence between the (conditional) measures with densities $p_\theta(\cdot | \vec{X}_0)$ and $p_{\theta_0}(\cdot | \vec{X}_0)$. The *Kullback-Leibler divergence* $\int \log(p/q) dP$ between two probability measures P and Q (with densities p and q relative to some measure) is always nonnegative, and it is zero if and only if the two measures are the same. This yields the following lemma.

13.4 Lemma. *The function $M: \Theta \rightarrow \mathbb{R}$ defined in (13.5) satisfies $M(\theta) \leq M(\theta_0)$ for every $\theta \in \Theta$, with equality if and only if the conditional distribution of X_1 given $\vec{X}_0 = \vec{x}_0$ is identical when computed for θ and θ_0 , for almost every \vec{x}_0 under the distribution of \vec{X}_0 under θ_0 .*

Proof. The inequality $\log x \leq 2(\sqrt{x} - 1)$, valid for $x > 0$, yields, for any two probability measures p and q relative to some measure μ ,

$$\int \log \frac{q}{p} p d\mu \leq \int 2 \left(\sqrt{\frac{q}{p}} - 1 \right) p d\mu = - \int (\sqrt{q} - \sqrt{p})^2 d\mu.$$

It follows that $\int \log(p/q) p d\mu$ is nonnegative, and equal to zero if and only if $p = q$ almost everywhere under μ . We apply this with p and q equal to the densities $x_1 \mapsto p_{\theta_0}(x_1 | \vec{X}_0)$ and $x_1 \mapsto p_\theta(x_1 | \vec{X}_0)$, respectively, to the inner integral in the right side of the expression for $M(\theta) - M(\theta_0)$ preceding the lemma, and conclude that this is nonnegative. Moreover, it is zero if and only if the two conditional laws are identical. The whole expression, including the outer expectation E_{θ_0} , is nonnegative, and vanishes only if the inner integral is zero for almost every \vec{x}_0 . ■

Under the reasonable assumption that each value of θ indexes a different underlying (conditional) distribution of the time series X_t (“identifiability of θ ”), we conclude that the map $\theta \mapsto M(\theta)$ possesses a unique absolute maximum at $\theta = \theta_0$.

The convergence of the criterion functions M_n to M , and the definitions of $\hat{\theta}_n$ and θ_0 as their points of maximum suggest that $\hat{\theta}_n$ converges to θ_0 . In other words, we expect the maximum likelihood estimators to be consistent for the “true” value θ_0 . This argument can be made mathematically rigorous, for instance by imposing additional conditions that guarantee the uniform convergence of M_n to M . See e.g. Theorem 3.17.

13.2.2 Asymptotic Normality

If it is true that $\hat{\theta}_n \rightarrow \theta_0$, then the question poses itself to characterize the rate at which the difference $\hat{\theta}_n - \theta_0$ converges to zero and to find a possible limit distribution for the rescaled difference. We shall assume that the parameter set Θ is a subset of \mathbb{R}^d , and establish the asymptotic normality of the sequence $\sqrt{n}(\hat{\theta}_n - \theta_0)$, under smoothness conditions on the contrast function $\theta \mapsto M_n(\theta)$ we shall.

We assume that the gradient $\dot{M}_n(\theta)$ and second derivative matrix $\ddot{M}_n(\theta)$ of the map $\theta \mapsto M_n(\theta)$ exist and are continuous. Because $\hat{\theta}_n$ is a point of maximum of M_n , it satisfies the stationary equation $\dot{M}_n(\hat{\theta}_n) = 0$ if $\hat{\theta}_n$ is an inner point of the parameter set. As we assume consistency of $\hat{\theta}_n$, this is the case with probability tending to 1 if θ_0 is an inner point of Θ , as we shall assume. In the case that the parameter is one-dimensional, Taylor's theorem shows that there exists a point $\tilde{\theta}_n$ on the line segment between θ_0 and $\hat{\theta}_n$ such that

$$0 = \dot{M}_n(\hat{\theta}_n) = \dot{M}_n(\theta_0) + \ddot{M}_n(\tilde{\theta}_n)(\hat{\theta}_n - \theta_0).$$

This can be rewritten as

$$\sqrt{n}(\hat{\theta}_n - \theta_0) = -(\ddot{M}_n(\tilde{\theta}_n))^{-1} \sqrt{n} \dot{M}_n(\theta_0).$$

Taylor's theorem does not apply in the same way to higher-dimensional parameters, for which the function \dot{M}_n is vector-valued. In that case we can apply the theorem to every coordinate function of \dot{M}_n , giving the second last display (which is now vector-valued) for every coordinate, but possibly with a different point $\tilde{\theta}_n$ for every coordinate. Abusing notation we shall omit the dependence on the coordinate and write the resulting matrix of gradients again as $\ddot{M}_n(\tilde{\theta}_n)$. We have

$$\sqrt{n} \dot{M}_n(\theta) = \frac{1}{\sqrt{n}} \sum_{i=1}^n \partial / \partial \theta \log p_\theta(X_t | \vec{X}_{t-1}), \quad \ddot{M}_n(\theta) = \frac{1}{n} \sum_{i=1}^n \partial^2 / \partial \theta^2 \log p_\theta(X_t | \vec{X}_{t-1}).$$

The matrices $\ddot{M}_n(\theta)$ are averages and hence the ergodic theorem guarantees their convergence in probability to a fixed matrix under reasonable conditions. Because $\hat{\theta}_n \xrightarrow{P} \theta_0$, it is a reasonable assumption that the matrices $\ddot{M}_n(\tilde{\theta}_n)$ and $\ddot{M}_n(\theta_0)$ possess the same limit. If we can also show that the sequence $\sqrt{n} \dot{M}_n(\theta_0)$ converges in distribution, then we can conclude that the sequence $\sqrt{n}(\hat{\theta}_n - \theta_0)$ converges in distribution, by Slutsky's lemma.

The convergence of the sequence $\sqrt{n} \dot{M}_n(\theta_0)$ can be established by the martingale central limit theorem, Theorem 4.16. To see this, first differentiate the identity $\int p_\theta(x_1 | \vec{x}_0) d\mu(x_1) = 1$ twice to verify (under regularity conditions) that

$$\int \dot{p}_\theta(x_1 | \vec{x}_0) d\mu(x_1) = \int \ddot{p}_\theta(x_1 | \vec{x}_0) d\mu(x_1) = 0.$$

The function $\theta \mapsto \ell_\theta = \log p_\theta$ possesses derivatives $\dot{\ell}_\theta = \dot{p}_\theta / p_\theta$ and $\ddot{\ell}_\theta = \ddot{p}_\theta / p_\theta - \dot{\ell}_\theta \dot{\ell}_\theta^T$. Combination with the preceding display yields conditional versions of the *Bartlett identities* “expectation of score function is zero” and “expectation of observed information is

minus the Fisher information”:

$$(13.6) \quad \begin{aligned} E_\theta \left(\dot{\ell}_\theta(X_1 | \vec{X}_0) | \vec{X}_0 \right) &= 0, \\ -E_\theta \left(\ddot{\ell}_\theta(X_1 | \vec{X}_0) | \vec{X}_0 \right) &= E_\theta \left(\dot{\ell}_\theta \dot{\ell}_\theta^T(X_1 | \vec{X}_0) | \vec{X}_0 \right) = \text{Cov}_\theta(\dot{\ell}_\theta(X_1 | \vec{X}_0) | \vec{X}_0). \end{aligned}$$

The first identity shows that the sequence $n\dot{M}_n(\theta) = \sum_{t=1}^n \dot{\ell}_\theta(X_t | \vec{X}_{t-1})$ is a martingale under the true measure specified by the parameter θ . Under reasonable conditions the martingale central limit theorem yields that the sequence $\sqrt{n}\dot{M}_n(\theta)$ is asymptotically normal with mean zero and covariance matrix

$$I_\theta = \text{Cov}_\theta(\dot{\ell}_\theta(X_1 | \vec{X}_0)).$$

By the second identity $E_\theta \ddot{M}_n(\theta) = -I_\theta$ and hence we may expect that $\ddot{M}_n(\theta) \xrightarrow{P} -I_\theta$ under θ , by the ergodic theorem. Combining this with Slutsky’s lemma as indicated before, we find that, under the true parameter θ_0 ,

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N(0, I_{\theta_0}^{-1}).$$

The matrix I_θ is known as the *Fisher information matrix* (average per observation). Typically, it can also be found as the limits

$$\begin{aligned} I_{n,\theta} &:= \frac{1}{n} E_\theta \frac{\partial}{\partial \theta} \log p_\theta(X_1, \dots, X_n) \frac{\partial}{\partial \theta} \log p_\theta(X_1, \dots, X_n)^T \rightarrow I_\theta, \\ &\quad -\frac{1}{n} \frac{\partial^2}{\partial \theta^2} \log p_\theta(X_1, \dots, X_n)_{|\theta=\hat{\theta}_n} \rightarrow I_\theta. \end{aligned}$$

The expression on the left in the second line is minus the second derivative matrix of the likelihood surface (times $1/n$) at the maximum likelihood estimator, and is known as the *observed information*. As it gives an estimate for the inverse of the asymptotic covariance matrix of the sequence $\sqrt{n}(\hat{\theta}_n - \theta)$ under θ , a “large” observed information (strongly curved likelihood surface) indicates that the maximum likelihood estimator has small asymptotic covariance.

The first line of the preceding display connects the matrix I_θ to the definition of the Fisher information for arbitrary observations, as it appears in the *Cramér-Rao bound* for the variance of unbiased estimators. According to the Cramér-Rao theorem, the covariance matrix of any unbiased estimator T_n of θ satisfies

$$\text{Cov}_\theta T_n \geq \frac{1}{n} I_{n,\theta}^{-1}.$$

The preceding informal derivation suggests that the asymptotic covariance matrix of the sequence $\sqrt{n}(\hat{\theta}_n - \theta)$ under θ is equal to I_θ^{-1} . We interpret this as saying that the maximum likelihood estimator is asymptotically of minimal variance, or *asymptotically efficient*.

For a rigorous proof of the asymptotic normality of the maximum likelihood estimator, and a precise formulation of its asymptotic efficiency (based on local asymptotic normality), see ??

13.5 EXERCISE. Compute the conditional maximum likelihood estimator for (θ, σ^2) in a stationary, causal AR(1) model $X_t = \theta X_{t-1} + Z_t$ with Gaussian innovations Z_t . What is its limit distribution? Calculate the Fisher information matrix I_θ .

13.6 EXERCISE. Find the pair of (conditional) likelihood equations $\dot{M}_n(\alpha, \theta) = 0$ for estimating the parameters (α, θ) in an ARCH(1) model. Verify the martingale property of $n\dot{M}_n(\alpha, \theta)$.

13.3 Asymptotics under Misspecification

Specification of a correct statistical model for a given time series is generally difficult, and it is typically hard to decide which of two given reasonable models is the better one. This observation is often taken as motivation for modelling a time series as a Gaussian series, Gaussianity being considered as good as any other specification and Gaussian likelihoods being relatively easy to handle. Meanwhile the validity of the Gaussian assumption may not really be accepted. It is therefore important, in time series analysis even more than in statistics for replicated experiments, to consider the behaviour of estimation procedures under misspecification of a model.

Consider an estimator $\hat{\theta}_n$ defined as the point of maximum of a likelihood function of a model that possibly does not contain the true distribution of the observations. It is again easier to consider the pseudo likelihood (13.2) than the true likelihood. The misspecified maximum pseudo likelihood estimator is still the point of maximum of the map $\theta \mapsto M_n(\theta)$ defined in (13.4). For the asymptotic analysis of $\hat{\theta}_n$ we again apply the ergodic theorem to see that $M_n(\theta) \rightarrow M(\theta)$ almost surely, for $M(\theta)$ the expectation of $M_n(\theta)$, defined by

$$(13.7) \quad M(\theta) = \mathbb{E} \log p_\theta(X_1 | \vec{X}_0) = \mathbb{E} \int \log p_\theta(x_1 | \vec{X}_0) p(x_1 | \vec{X}_0) d\mu(x_1).$$

The difference with the foregoing is that presently the expectation is taken under the true model for the series X_t , which may or may not be representable through one of the parameters θ . In the display this is indicated by denoting a general expectation by the symbol \mathbb{E} (and not \mathbb{E}_{θ_0}) and a generic density by p (and not p_{θ_0}). However, the same reasoning suggests that $\hat{\theta}_n$ converges in probability to a value θ_0 that maximizes the map $\theta \mapsto M(\theta)$. Without further specification of the model and the true distribution of the time series, there is little more we can say about this maximizing value than that it gives conditional densities $p_{\theta_0}(\cdot | \vec{x}_0)$ that are, on the average, closest to the true conditional densities $p(\cdot | \vec{x}_0)$ of the time series in terms of the Kullback-Leibler divergence.

Having ascertained that the sequence $\hat{\theta}_n$ ought to converge to a limit, most of the subsequent arguments to establish asymptotic normality of the sequence $\sqrt{n}(\hat{\theta}_n - \theta_0)$ go through, also under misspecification, provided that

$$(13.8) \quad \mathbb{E}(\dot{\ell}_{\theta_0}(X_1 | \vec{X}_0) | \vec{X}_0) = 0, \quad \text{a.s..}$$

Under this condition the sequence $n\dot{M}_n(\theta_0)$ is still a martingale, and $\sqrt{n}\dot{M}_n(\theta_0)$ may be expected to be asymptotically normal by the martingale central limit theorem. By the assumed ergodicity of the series X_t the sequence $\dot{M}_n(\theta_0)$ will still converge to a fixed matrix, and the same may be expected to be true for the sequence of second derivatives $\ddot{M}_n(\hat{\theta}_n)$ evaluated at a point between $\hat{\theta}_n$ and θ_0 . A difference is that the asymptotic covariance matrix Σ_{θ_0} of the sequence $\sqrt{n}\dot{M}_n(\theta_0)$ and the limit R_{θ_0} of the sequence $\ddot{M}_n(\theta_0)$ may no longer be each other's negatives (as it the case under correct specification by the second Bartlett identity (13.6)). The conclusion will therefore take the more complicated form

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N(0, R_{\theta_0}^{-1} \Sigma_{\theta_0} (R_{\theta_0}^{-1})^T).$$

The covariance of this normal limit distribution is referred to as the *sandwich formula*.

Thus under (13.8) we may expect that the sequence $\hat{\theta}_n$ will converge rapidly to a limit θ_0 . Then “fitting the wrong model” will be useful as long as the density p_{θ_0} (or an aspect of interest of it) is sufficiently close to the true density of the time series.

Condition (13.8) is odd, and not automatically satisfied. It is certainly satisfied if the point of maximum θ_0 of the map $\theta \mapsto M(\theta)$ is such that for every \vec{x}_0 it is also a point of maximum of the map

$$(13.9) \quad \theta \mapsto \int \log p_{\theta}(x_1 | \vec{x}_0) p(x_1 | \vec{x}_0) d\mu(x_1).$$

This is not necessarily the case, as the points of maxima of these functions may depend on the different values of \vec{x}_0 . The point θ_0 is by definition the point of maximum of the average of these functions over \vec{x}_0 , weighted by the true distribution of \vec{X}_0 . Failure of (13.8) does not necessarily mean that the sequence $\sqrt{n}(\hat{\theta}_n - \theta_0)$ is not asymptotically normally distributed, but it does mean that we cannot apply the martingale central limit theorem, as in the preceding argument.

In the next section we discuss a major example of possible misspecification: estimating a parameter by Gaussian maximum likelihood. The following example concerns GARCH processes, and illustrates that some misspecifications are harmless, whereas others may cause trouble.

13.7 Example (GARCH). As found in Example 13.3, the pseudo likelihood for a GARCH(p, q) process takes the form

$$\prod_{t=1}^n \frac{1}{\sigma_t(\theta)} p_Z\left(\frac{X_t}{\sigma_t(\theta)}\right),$$

where p_Z is the density of the innovations and $\theta = (\alpha, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$. In Chapter 9 it was noted that a t -density p_Z may be appropriate to explain the observed leptokurtic tails of financial time series. However, the Gaussian density $p_Z(z) = \exp(-\frac{1}{2}z^2)/\sqrt{2\pi}$ is more popular for likelihood based inference for GARCH processes. The corresponding Gaussian log pseudo likelihood is up to additive and multiplicative constants equal to

$$\theta \mapsto -\frac{1}{n} \sum_{t=1}^n \log \sigma_t^2(\theta) - \frac{1}{n} \sum_{t=1}^n \frac{X_t^2}{\sigma_t^2(\theta)}.$$

The expectation of this criterion function can be written as

$$M(\theta) = -E\left(\log \sigma_1^2(\theta) + \frac{E(X_1^2 | \mathcal{F}_0)}{\sigma_1^2(\theta)}\right).$$

Both the expectation and the conditional expectation on the right side are taken relative to the true distribution of the time series. (The outermost expectation is relative to the vector \vec{X}_0 that is hidden in $\sigma_1^2(\theta)$ and in $E(X_1^2 | \mathcal{F}_0)$.) The sequence $\hat{\theta}_n$ may be expected to converge to the point of maximum of the map $\theta \mapsto M(\theta)$.

Suppose that the GARCH equation (9.1) for the conditional variances is correctly specified, but allow the true density of the innovations to be not standard normal. Thus $E(X_1^2 | \mathcal{F}_0) = \sigma_1^2(\theta_0)$ for the true parameter θ_0 and hence

$$(13.10) \quad M(\theta) = -E\left(\log \sigma_1^2(\theta) + \frac{\sigma_1^2(\theta_0)}{\sigma_1^2(\theta)}\right).$$

For every fixed σ_0^2 , the map $\sigma^2 \mapsto \log \sigma^2 + \sigma_0^2/\sigma^2$ assumes its minimal value on the domain $(0, \infty)$ at $\sigma^2 = \sigma_0^2$. It follows that the map $\theta \mapsto M(\theta)$ is maximized at $\theta = \theta_0$ no matter the distribution of \vec{X}_0 that determines the expectation E that defines $M(\theta)$.

We conclude that the use of the Gaussian density for p_Z will lead (under regularity conditions) to consistent estimators $\hat{\theta}_n$ for the coefficients of the GARCH equation as long as the conditional variance model is correctly specified. In particular, the true density p_Z of the innovations need not be Gaussian. As shown in the preceding arguments, this pleasant fact is the result of the fact that the likelihood based on choosing the normal density for p_Z depends on the observations X_t only through a linear function of the squares X_t^2 . For another choice of density p_Z , such as a t -density, this is not true, and we cannot hope to be guarded against misspecification in that case.

The maximizing parameter θ_0 maximizes the expression $\theta \mapsto \log \sigma_1^2(\theta) + \sigma_1^2(\theta_0)/\sigma_1^2(\theta)$ inside the brackets in (13.10) over θ , for any fixed value of \vec{X}_0 . In the general notation this corresponds to maximizing the inner integral in (13.7), for every value of \vec{X}_0 . Therefore (13.8) is satisfied, and we expect the sequence $\sqrt{n}(\hat{\theta}_n - \theta_0)$ to be asymptotically normal, with asymptotic variance given by the sandwich formula.

These conclusions are all conditional on the assumption that the conditional variance model stipulated by the GARCH model is correct. Because the parameter θ has a meaning only relative to this model, this does not seem an important restriction. \square

13.4 Gaussian Likelihood

A *Gaussian time series* is a time series X_t such that the joint distribution of every finite subvector $(X_{t_1}, \dots, X_{t_n})$ of the series possesses a multivariate normal distribution. In particular, the vector (X_1, \dots, X_n) is multivariate normally distributed, and hence its distribution is completely specified by a mean vector $\mu_n \in \mathbb{R}^n$ and an $(n \times n)$ covariance

matrix Γ_n . For a stationary time series X_t this matrix has entries $(\Gamma_n)_{s,t} = \gamma_X(s-t)$, for γ_X the auto-covariance function of X_t .

We assume that both the mean μ_n and the covariance function γ_X can be expressed in a parameter θ of fixed dimension, so that we can write $\mu_n = \mu_n(\theta)$ and $\Gamma_n = \Gamma_n(\theta)$. Then the likelihood function under the assumption that X_t is a Gaussian time series is the multivariate normal density viewed as function of the parameter and takes the form

$$(13.11) \quad \theta \mapsto \frac{1}{(2\pi)^{n/2}} \frac{1}{\sqrt{\det \Gamma_n(\theta)}} e^{-\frac{1}{2}(\bar{X}_n - \mu_n(\theta))^T \Gamma_n(\theta)^{-1}(\bar{X}_n - \mu_n(\theta))}.$$

We refer to this function as the *Gaussian likelihood*, and to its point of maximum $\hat{\theta}_n$, if it exists, as the *maximum Gaussian likelihood estimator*. The Gaussian likelihood and the corresponding estimator are commonly used, also in the case that the time series X_t is non-Gaussian.

Maximum Gaussian likelihood is closely related to the method of least squares, described in Section 11.3. We can see this using the likelihood factorization (13.1). For a Gaussian process the conditional densities $p_\theta(x_t | X_{t-1}, \dots, X_1)$ are univariate normal densities with means $E_\theta(X_t | X_{t-1}, \dots, X_1)$ and variances $v_t(\theta)$ equal to the prediction errors. (Cf. Exercise 13.8.) Furthermore, the best nonlinear predictor $E_\theta(X_t | X_{t-1}, \dots, X_1)$ is automatically a linear combination of the predicting variables and hence coincides with the best linear predictor $\Pi_{t-1}X_t(\theta)$. This shows that the factorization (13.1) reduces to

$$\prod_{t=1}^n \frac{1}{\sqrt{v_t(\theta)}} \phi\left(\frac{X_t - \Pi_{t-1}X_t(\theta)}{\sqrt{v_t(\theta)}}\right).$$

Maximizing this relatively to θ is equivalent to maximizing its logarithm, which can be written in the form

$$(13.12) \quad \theta \mapsto -\frac{n}{2} \log(2\pi) - \frac{1}{2} \sum_{t=1}^n \log v_t(\theta) - \frac{1}{2} \sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\theta))^2}{v_t(\theta)}.$$

This function differs in form from the least squares criterion function (11.6) only in the presence of the function $\theta \mapsto -\frac{1}{2} \sum_{t=1}^n \log v_t(\theta)$. In situations where this function is almost constant least squares and Gaussian maximum likelihood estimators are almost the same.

13.8 EXERCISE. Suppose that the vector (X_1, \dots, X_t) possesses a multivariate normal distribution. Show that the conditional distribution of X_t given (X_1, \dots, X_{t-1}) is normal with mean the best linear predictor $\Pi_{t-1}X_t$ of X_t based on X_1, \dots, X_{t-1} and variance the prediction error $v_t = \text{var}(X_t - \Pi_{t-1}X_t)$. [Reduce to the case that the unconditional mean is 0. Let Y be the best linear predictor of X_t based on X_1, \dots, X_{t-1} . Show that $(X_t - Y, \bar{X}_{t-1})$ is multivariate normal with zero covariance between $X_t - Y$ and \bar{X}_{t-1} . Conclude that the variables are independent, and use this to deduce the conditional distribution of $X_t = (X_t - Y) + Y$.]

13.9 Example (Autoregression). For causal stationary auto-regressive processes of order p and $t > p$ the best linear predictor of X_t is equal to $\phi_1 X_{t-1} + \dots + \phi_p X_{t-p}$. Thus

the innovations $X_t - \Pi_{t-1}X_t$ are equal to the noise inputs Z_t , and the prediction errors v_t are equal to $\sigma^2 = \mathbb{E}Z_t^2$ for $t > p$. Thus the function $\theta \mapsto -\frac{1}{2} \sum_{t=1}^n \log v_t(\theta)$ in the formula for the Gaussian likelihood is approximately equal to $-\frac{1}{2}n \log \sigma^2$, if n is much bigger than p . The log Gaussian likelihood is approximately equal to

$$-\frac{n}{2} \log(2\pi) - \frac{1}{2}n \log \sigma^2 - \frac{1}{2} \sum_{t=p+1}^n \frac{(X_t - \phi_1 X_{t-1} - \cdots - \phi_p X_{t-p})^2}{\sigma^2}.$$

For a fixed σ^2 maximization relative to ϕ_1, \dots, ϕ_p is equivalent to minimization of the sum of squares and hence gives identical results as the method of least squares discussed in Sections 11.1 and 11.3. Maximization relative to σ^2 gives (almost) the Yule-Walker estimator discussed in Section 11.1. \square

13.10 Example (ARMA). In ARMA models the parameter σ^2 enters as a multiplicative factor in the covariance function (cf. Section 11.3). This implies that the log Gaussian likelihood function can be written in the form, with $\theta = (\phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$,

$$-\frac{n}{2} \log(2\pi) - \frac{n}{2} \log \sigma^2 - \frac{1}{2} \sum_{t=1}^n \log \tilde{v}_t(\theta) - \frac{1}{2} \sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\theta))^2}{\sigma^2 \tilde{v}_t(\theta)}.$$

Differentiating this with respect to σ^2 we see that for every fixed θ , the Gaussian likelihood is maximized relative to σ^2 by

$$\hat{\sigma}^2(\theta) = \frac{1}{n} \sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\theta))^2}{\tilde{v}_t(\theta)}.$$

Substituting this expression in the log Gaussian likelihood, we see that the maximum Gaussian likelihood estimator of θ maximizes the function

$$\theta \mapsto -\frac{n}{2} \log(2\pi) - \frac{n}{2} \log \hat{\sigma}^2(\theta) - \frac{1}{2} \sum_{t=1}^n \log \tilde{v}_t(\theta) - \frac{n}{2}.$$

The latter function is called the *profile log likelihood* for θ , and the elimination of the parameter σ^2 is referred to as *concentrating out* this parameter. We can drop the constant terms in the profile log likelihood and conclude that the maximum Gaussian likelihood estimator $\hat{\theta}$ for θ minimizes

$$(13.13) \quad \theta \mapsto \log \frac{1}{n} \sum_{t=1}^n \frac{(X_t - \Pi_{t-1}X_t(\theta))^2}{\tilde{v}_t(\theta)} + \frac{1}{n} \sum_{t=1}^n \log \tilde{v}_t(\theta).$$

The maximum Gaussian likelihood estimator for σ^2 is $\hat{\sigma}^2(\hat{\theta})$.

For causal, invertible stationary ARMA processes the innovations $X_t - \Pi_{t-1}X_t(\theta)$ are for large t approximately equal to Z_t , whence $\tilde{v}_t(\theta) \approx \mathbb{E}Z_t^2/\sigma^2 = 1$. (Cf. the discussion in Section 8.4. In fact, it can be shown that $|\tilde{v}_t - 1| \leq c^t$ for some $0 < c < 1$ and sufficiently large t .) This suggests that the criterion function (13.13) does not change much if we drop its second term and retain only the sum of squares. The corresponding approximate maximum Gaussian likelihood estimator is precisely the least squares estimator, discussed in Section 11.3. \square

13.11 Example (GARCH). The distribution of a GARCH process $X_t = \sigma_t Z_t$ depends on the distribution of the innovations Z_t , but is rarely (or never?) Gaussian. Nevertheless we may try and apply the method of Gaussian likelihood.

Because a GARCH series is a white noise series, the mean vector of (X_1, \dots, X_n) is zero and its covariance matrix is diagonal. For a stationary GARCH process the diagonal elements are identical and can be expressed in the parameters of the GARCH process. (For instance $EX_t^2 = \alpha/(1 - \phi - \theta)$ for the GARCH(1,1).) As the Gaussian likelihood depends on the parameters of the model only through the variances $v_t^2 = EX_t^2$, this likelihood can at best yield good estimators for functions of this variance. The GARCH parameters cannot be recovered from this. For instance, we cannot estimate the parameter (α, ϕ, θ) of a GARCH (1, 1) process from a criterion function that depends on these parameters only through $\alpha/(1 - \phi - \theta)$.

We conclude that the method of Gaussian likelihood is useless for GARCH processes. We note that the “Gaussian likelihood” as discussed in this section is not the same as the GARCH likelihood under the assumption that the innovations Z_t are Gaussian (cf. Example 13.3). The Gaussian likelihood is similar in form, but with the conditional variances σ_t^2 in the latter replaced by their expectations. \square

In the preceding examples we have seen that for AR and ARMA processes the Gaussian maximum likelihood estimators are, asymptotically as $n \rightarrow \infty$, close to the least squares estimators. The following theorem shows that the asymptotic behaviour of these estimators is identical to that of the least squares estimators, which is given in Theorem 11.19.

13.12 Theorem. *Let X_t be a causal, invertible stationary ARMA(p, q) process relative to an i.i.d. sequence Z_t . Then the Gaussian maximum likelihood estimator satisfies*

$$\sqrt{n} \left(\begin{pmatrix} \hat{\vec{\phi}}_p \\ \hat{\vec{\theta}}_q \end{pmatrix} - \begin{pmatrix} \vec{\phi}_p \\ \vec{\theta}_q \end{pmatrix} \right) \rightsquigarrow N(0, \sigma^2 J_{\vec{\phi}_p, \vec{\theta}_q}^{-1}),$$

where $J_{\vec{\phi}_p, \vec{\theta}_q}$ is the covariance matrix of $(U_{-1}, \dots, U_{-p}, V_{-1}, \dots, V_{-q})$ for stationary autoregressive processes U_t and V_t satisfying $\phi(B)U_t = \theta(B)V_t = Z_t$.

Proof. The proof is long and technical. See Brockwell and Davis (1991), pages 375–396, Theorem 10.8.2. \blacksquare

The theorem does not assume that the time series X_t itself is Gaussian; it uses the Gaussianity only as a working hypothesis to define maximum likelihood estimators. Apparently, using “the wrong likelihood” still leads to reasonable estimators. This is plausible, because Gaussian maximum likelihood estimators are asymptotically equivalent to least squares estimators and the method of least squares can be motivated without reference to Gaussianity. Alternatively, it can be explained from consideration of the Kullback-Leibler divergence, as in Section 13.3.

On the other hand, in the case that the series X_t is not Gaussian the true maximum likelihood estimators (if the true model, i.e. the true distribution of the noise factors Z_t is

known) are likely to perform better than the least squares estimators. In this respect time series analysis is not different from the situation for replicated experiments. An important difference is that in practice non-Gaussianity may be difficult to detect, other plausible distributions difficult to motivate, and other likelihoods be computationally complex. The Gaussian distribution is therefore frequently adopted as a working hypothesis.

* 13.4.1 Whittle Estimators

Because the Gaussian likelihood function of a mean zero time series depends on the autocovariance function only, it can be helpful to write it in terms of the spectral density. The covariance matrix of a vector (X_1, \dots, X_n) belonging to a stationary time series X_t with spectral density f_X can be written as $\Gamma_n(f_X)$, for

$$\Gamma_n(f) = \left(\int_{-\pi}^{\pi} e^{i(s-t)\lambda} f(\lambda) d\lambda \right)_{s,t=1,\dots,n}.$$

Thus if the time series X_t has spectral density f_θ under the parameter θ and mean zero, then the log Gaussian likelihood can be written in the form

$$-n \log(2\pi) - \frac{1}{2} \log \det \Gamma_n(f_\theta) - \frac{1}{2} \vec{X}_n^T \Gamma_n(f_\theta)^{-1} \vec{X}_n.$$

Maximizing this expression over θ is equivalent to maximizing the Gaussian likelihood as discussed previously, but gives a different perspective. For instance, to fit an ARMA process we would maximize this expression over all “rational spectral densities” of the form $\sigma^2 |\theta(e^{-i\lambda})|^2 / |\phi(e^{-i\lambda})|^2$.

The true advantage of writing the likelihood in spectral notation is that it suggests a convenient approximation. The *Whittle approximation* is defined as

$$-\frac{n}{2} \log(2\pi) - \frac{n}{4\pi} \int_{-\pi}^{\pi} \log f_\theta(\lambda) d\lambda - \frac{n}{4\pi} \int_{-\pi}^{\pi} \frac{I_n(\lambda)}{f_\theta(\lambda)} d\lambda,$$

where $I_n(\lambda)$ is the periodogram of the time series X_t , as defined in Section 12.2. This approximation results from the following approximations, valid for sufficiently regular functions f ,

$$\begin{aligned} \Gamma_n(f)^{-1} &\approx \Gamma_n\left(\frac{1}{f}\right) \frac{1}{4\pi^2}, \\ \frac{1}{n} \log \det \Gamma_n(f) &\approx \log(2\pi) + \frac{1}{2\pi} \int_{-\pi}^{\pi} \log f(\lambda) d\lambda, \end{aligned}$$

combined with the identity

$$\frac{1}{n} \vec{X}_n^T \Gamma_n(f) \vec{X}_n = 2\pi \int_{-\pi}^{\pi} I_n(\lambda) f(\lambda) d\lambda.$$

The approximations are made precise in Lemma ?? (Kolmogorov-Szegö), whereas the identity follows by some algebra.

13.13 EXERCISE. Verify the identity in the preceding display.

The Whittle approximation is both more convenient for numerical manipulation and more readily amenable to theoretical analysis. The point of maximum $\hat{\theta}_n$ of the Whittle approximation, if it exists, is known as the *Whittle estimator*. Conceptually, this comes down to a search in the class of spectral densities f_θ defined through the model.

13.14 Example (Autoregression). For an auto-regressive time series of fixed order the Whittle estimators are identical to the Yule-Walker estimators, which are also (almost) identical to the maximum Gaussian likelihood estimators. This can be seen as follows.

The Whittle estimators are defined by maximizing the Whittle approximation over all spectral densities of the form $f_\theta(\lambda) = \sigma^2 / |\phi(e^{-i\lambda})|^2$, for ϕ the auto-regressive polynomial $\phi(z) = 1 - \phi_1 z - \dots - \phi_p z^p$. By the Kolmogorov-Szegö formula (See ??), or direct computation, $\int \log f_\theta(\lambda) d\lambda = 2\pi \log(\sigma^2/2\pi)$ is independent of the parameters ϕ_1, \dots, ϕ_p . Thus the stationary equations for maximizing the Whittle approximation with respect to the parameters take the form

$$\begin{aligned} 0 &= \frac{\partial}{\partial \phi_k} \int \frac{I_n(\lambda)}{f_\theta(\lambda)/\sigma^2} d\lambda = \frac{\partial}{\partial \phi_k} \int \phi(e^{i\lambda}) \phi(e^{-i\lambda}) I_n(\lambda) d\lambda \\ &= \int \left[-e^{i\lambda k} \phi(e^{-i\lambda}) - \phi(e^{i\lambda}) e^{-i\lambda k} \right] I_n(\lambda) d\lambda \\ &= -2 \operatorname{Re} \int \left[e^{i\lambda k} - \phi_1 e^{i\lambda(k-1)} - \dots - \phi_p e^{i\lambda(k-p)} \right] I_n(\lambda) d\lambda \\ &= -2 \operatorname{Re} \left[\hat{\gamma}_n^*(k) - \phi_1 \hat{\gamma}_n^*(k-1) - \dots - \phi_p \hat{\gamma}_n^*(k-p) \right], \end{aligned}$$

because $\hat{\gamma}_n^*(h) = n^{-1} \sum_{t=1}^{n-|h|} X_{t+|h|} X_t$ are the Fourier coefficients of the function I_n for $|h| < n$, by (12.2). Thus the stationary equations are the Yule-Walker equations, apart from the fact that the observations have been centered at mean zero, rather than at \bar{X}_n . \square

13.15 EXERCISE. Derive the Whittle estimator for σ^2 for an autoregressive process.

If we write $I_n(f)$ for $\int I_n(\lambda) f(\lambda) d\lambda$, then a Whittle estimator is a point of minimum of the map

$$\theta \mapsto M_n(\theta) = \int_{-\pi}^{\pi} \log f_\theta(\lambda) d\lambda + I_n\left(\frac{1}{f_\theta}\right).$$

In Section 12.4 it is shown that the sequence $\sqrt{n}(I_n(f) - \int f f_X d\lambda)$ is asymptotically normally distributed with mean zero and covariance matrix $\Sigma^2(f)$, under some conditions. This implies that the sequence $M_n(\theta)$ converges for every fixed θ in probability to

$$M(\theta) = \int \log f_\theta(\lambda) d\lambda + \int \frac{f_X}{f_\theta}(\lambda) d\lambda.$$

By reasoning as in Section 13.1 we expect that the Whittle estimators $\hat{\theta}_n$ will be asymptotically consistent for the parameter θ_0 that minimizes the function $\theta \mapsto M(\theta)$.

If the true spectral density f_X takes the form $f_X = f_{\theta_0}$ for some parameter θ_0 , then this parameter is the minimizing value. Indeed, by the inequality $-\log x + (x - 1) \geq (\sqrt{x} - 1)^2$, valid for every $x \geq 0$,

$$M(\theta) - M(\theta_0) = \int \left(\log \frac{f_\theta}{f_{\theta_0}}(\lambda) + \frac{f_{\theta_0}}{f_\theta}(\lambda) - 1 \right) d\lambda \geq \int \left(\sqrt{\frac{f_{\theta_0}}{f_\theta}}(\lambda) - 1 \right)^2 d\lambda.$$

This shows that the function $\theta \mapsto M(\theta)$ possesses a minimum value at $\theta = \theta_0$, and this point of minimum is unique as soon as the parameter θ is identifiable from the spectral density.

To derive the form of the limit distribution of the Whittle estimators we replace $\dot{M}(\theta)$ by its linear approximation, as in Section 13.1, and obtain that

$$\sqrt{n}(\hat{\theta}_n - \theta_0) = -(\ddot{M}_n(\tilde{\theta}_n))^{-1} \sqrt{n} \dot{M}_n(\theta_0).$$

Denoting the gradient and second order derivative matrix of the function $\theta \mapsto \log f_\theta(\lambda)$ by $\dot{\ell}_\theta(\lambda)$ and $\ddot{\ell}_\theta(\lambda)$, we can write

$$\begin{aligned} \sqrt{n} \dot{M}_n(\theta) &= \int \dot{\ell}_\theta(\lambda) d\lambda - I_n \left(\frac{\dot{\ell}_\theta}{f_\theta} \right), \\ \ddot{M}_n(\theta) &= \int \ddot{\ell}_\theta(\lambda) d\lambda + I_n \left(\frac{\dot{\ell}_\theta \dot{\ell}_\theta^T - \ddot{\ell}_\theta}{f_\theta} \right). \end{aligned}$$

By the results of Section 12.4 the sequence $\sqrt{n} \dot{M}_n(\theta_0)$ converges in distribution to a normal distribution with mean zero and covariance matrix $\Sigma(\dot{\ell}_{\theta_0}/f_{\theta_0})$, under some conditions. Furthermore, the sequence $\ddot{M}_n(\theta_0)$ converges in probability to $\int \dot{\ell}_{\theta_0} \dot{\ell}_{\theta_0}^T(\lambda) d\lambda =: J_{\theta_0}$. If both are satisfied, then we obtain that

$$\sqrt{n}(\hat{\theta}_n - \theta_0) \rightsquigarrow N\left(0, J_{\theta_0}^{-1} \Sigma(\dot{\ell}_{\theta_0}/f_{\theta_0}) J_{\theta_0}^{-1}\right).$$

The asymptotic covariance is of the “sandwich form”.

If the time series X_t is Gaussian, then the Whittle likelihood is an approximation for the correctly specified likelihood, and the asymptotic covariance reduces to a simpler expression. In this case, since the kurtosis of the normal distribution is 0,

$$\Sigma(f) = 4\pi \int f f^T(\lambda) f_X^2(\lambda) d\lambda.$$

It follows that in the case, and with $f_X = f_{\theta_0}$, the asymptotic covariance of the sequence $\sqrt{n} \dot{M}_n(\theta_0)$ reduces to $4\pi J_{\theta_0}$, and the sandwich covariance reduces to $4\pi J_{\theta_0}^{-1}$.

13.16 Example (ARMA). The log spectral density of a stationary, causal, invertible ARMA(p, q) process with parameter vector $\theta = (\sigma^2, \phi_1, \dots, \phi_p, \theta_1, \dots, \theta_q)$ can be written in the form

$$\log f_\theta(\lambda) = \log \sigma^2 - \log(2\pi) + \log \theta(e^{i\lambda}) + \log \theta(e^{-i\lambda}) - \log \phi(e^{i\lambda}) - \log \phi(e^{-i\lambda}).$$

Straightforward differentiation shows that the gradient of this function is equal to

$$\dot{\ell}_\theta(\lambda) = \begin{pmatrix} \sigma^{-2} \\ \frac{e^{i\lambda k}}{\phi(e^{i\lambda})} + \frac{e^{-i\lambda k}}{\phi(e^{-i\lambda})} \\ \frac{e^{i\lambda l}}{\theta(e^{i\lambda})} + \frac{e^{-i\lambda l}}{\theta(e^{-i\lambda})} \end{pmatrix}_{k=1, \dots, p, l=1, \dots, q}$$

Here the second and third lines of the vector on the right are abbreviations of vectors of length p and q , obtained by letting k and l range over the values $1, \dots, p$ and $1, \dots, q$, respectively. The matrix $J_\theta = \int \dot{\ell}_\theta \dot{\ell}_\theta^T(\lambda) d\lambda$ takes the form

$$J_\theta = \begin{pmatrix} \frac{2\pi}{\sigma^4} & 0 & 0 \\ 0 & AR & MAAR \\ 0 & MAAR^T & MA \end{pmatrix},$$

where AR , MA , and $MAAR$ are matrices of dimensions $(p \times p)$, $(q \times q)$ and $(p \times q)$, respectively, which are described in more detail in the following. The zeros must be replicated to fulfill the dimension requirements, and result from calculations of the type, for $k \geq 1$,

$$\int_{-\pi}^{\pi} \frac{e^{i\lambda k}}{\phi(e^{i\lambda})} d\lambda = \frac{1}{i} \int_{|z|=1} \frac{z^{k-1}}{\phi(z)} dz = 0,$$

by Cauchy's theorem, because the function $z \mapsto z^{k-1}/\phi(z)$ is analytic on a neighbourhood of the unit disc, by the assumption of causality of the ARMA process.

Using the identity $(f + \bar{f})(g + \bar{g}) = 2 \operatorname{Re}(fg + f\bar{g})$ we can compute the (l, l') -element of the matrix MA as

$$\begin{aligned} 2 \operatorname{Re} \int \left[\frac{e^{i\lambda l}}{\theta(e^{i\lambda})} \frac{e^{i\lambda l'}}{\theta(e^{i\lambda})} + \frac{e^{i\lambda l}}{\theta(e^{i\lambda})} \frac{e^{-i\lambda l'}}{\theta(e^{-i\lambda})} \right] d\lambda \\ = 2 \operatorname{Re} \left(0 + \int \frac{e^{i\lambda(l-l')}}{|\theta(e^{i\lambda})|^2} d\lambda \right) = 2\gamma_V(l - l')2\pi, \end{aligned}$$

where V_t is a stationary auto-regressive process satisfying $\theta(B)V_t = Z_t$ for a white noise process Z_t of unit variance. The matrix AR can be expressed similarly as the covariance matrix of p consecutive elements of an auto-regressive process U_t satisfying $\phi(B)U_t = Z_t$. The (k, l) -element of the matrix $MAAR$ can be written in the form

$$2 \operatorname{Re} \int \left[\frac{e^{i\lambda k}}{\phi(e^{i\lambda})} \frac{e^{i\lambda l}}{\theta(e^{i\lambda})} + \frac{e^{i\lambda k}}{\phi(e^{i\lambda})} \frac{e^{-i\lambda l}}{\theta(e^{-i\lambda})} \right] d\lambda = 2 \operatorname{Re} \left(0 + 2\pi \int f_{UV}(\lambda) e^{i\lambda(k-l)} d\lambda \right).$$

Here $f_{UV}(\lambda) = 1/(2\pi\phi(e^{i\lambda})\theta(e^{-i\lambda}))$ is the cross spectral density of the auto-regressive processes U_t and V_t defined previously (using the same white noise process Z_t)(?). Hence

the integral on the far left is equal to 2π times the complex conjugate of the cross covariance $\gamma_{UV}(k-l)$.

Taking this all together we see that the matrix resulting from deleting the first row and first column from the matrix $J_\theta/(4\pi)$ results in the matrix $J_{\vec{\phi}_p, \vec{\theta}_q}$ that occurs in Theorem 13.12. Thus the Whittle estimators and maximum Gaussian likelihood estimators have asymptotically identical behaviour.

In view of the block structure in J_θ , the Whittle estimator for σ^2 is asymptotically independent of the estimators of the remaining parameters. \square

* 13.4.2 Gaussian Time Series

In this section we study the behaviour of the maximum likelihood estimators for general Gaussian time series in more detail. Thus $\hat{\theta}_n$ is the point of maximum of (13.11) (or equivalently (13.12)), and we study the properties of the sequence $\sqrt{n}(\hat{\theta}_n - \theta)$ under the assumption that the true density of (X_1, \dots, X_n) possesses the form (13.11), for some θ . For simplicity we assume that the time series is centered at mean zero, so that the model is completely parametrized by the covariance matrix $\Gamma_n(\theta)$. Equivalently, it is determined by the spectral density f_θ , which is related to the covariance matrix by

$$(\Gamma_n(\theta))_{s,t} = \int_{-\pi}^{\pi} e^{i(s-t)\lambda} f_\theta(\lambda) d\lambda.$$

It is easier to express conditions and results in terms of the spectral density f_θ , which is fixed, than in terms of the sequence of matrices $\Gamma_n(\theta)$. The asymptotic *Fisher information* for θ is defined as

$$I_\theta = \frac{1}{4\pi} \int_{-\pi}^{\pi} \frac{\partial \log f_\theta}{\partial \theta}(\lambda) \left(\frac{\partial \log f_\theta}{\partial \theta}(\lambda) \right)^T d\lambda.$$

13.17 Theorem. *Suppose that X_t is a Gaussian time series with zero mean and spectral density f_θ such that the map $\theta \mapsto f_\theta$ is one-to-one and the map $(\theta, \lambda) \mapsto f_\theta(\lambda)$ is three times continuously differentiable and strictly positive. Suppose that θ ranges over a bounded, open subset of \mathbb{R}^d . Then the maximum likelihood estimator $\hat{\theta}_n$ based on X_1, \dots, X_n satisfies $\sqrt{n}(\hat{\theta}_n - \theta) \rightsquigarrow N(0, I_\theta^{-1})$.*

Proof. See Azencott and Dacunha-Castelle (1984), Chapitre XIII. ■

The theorem is similar in form to the theorem for maximum likelihood estimators based on replicated experiments. If $p_{n,\theta}$ is the density of $\vec{X}_n = (X_1, \dots, X_n)$ (given in (13.11)), then it can be shown under the conditions of the theorem that

$$I_{n,\theta} := \frac{1}{n} \mathbb{E}_\theta \frac{\partial}{\partial \theta} \log p_{n,\theta}(\vec{X}_n) \left(\frac{\partial}{\partial \theta} \log p_{n,\theta}(\vec{X}_n) \right)^T \rightarrow I_\theta.$$

The left side of this display is the true (average) Fisher information (per observation) for θ based on \vec{X}_n , and this explains the name asymptotic Fisher information for I_θ . With this in mind the analogy with the situation for replicated experiments is perfect.

13.5 Model Selection

In the preceding sections and chapters we have studied estimators for the parameters of ARMA or GARCH processes assuming that the orders p and q are known a-priori. In practice reasonable values of p and q can be chosen from plots of the auto-correlation and the partial auto-correlation functions, followed by diagnostic checking after fitting a particular model. Alternatively (or in addition) we can estimate appropriate values of p and q and the corresponding parameters simultaneously from the data. The maximum likelihood method must then be augmented by penalization.

The value of the likelihood (13.1) depends on the dimension the parameter θ . If models of different dimension are available, then we can make the dependence explicit by denoting the log likelihood as, with d the dimension of the model,

$$\Lambda_n(\theta, d) = \sum_{t=1}^n \log p_{\theta, d}(X_t | X_{t-1}, \dots, X_1).$$

A first idea to select a reasonable dimension is to maximize the function Λ_n jointly over (θ, d) . This rarely works. The models of interest are typically nested in that a model of dimension d is a submodel of a model of dimension $d+1$. The maximum over (θ, d) is then taken for the largest possible dimension. To counter this preference for large dimension we can introduce a *penalty function*. Instead of Λ_n we maximize

$$(\theta, d) \mapsto \Lambda_n(\theta, d) - \phi_n(d),$$

where ϕ_n is a fixed function that takes large values for large values of its argument. Maximizing this function jointly over (θ, d) must strike a balance between maximizing Λ_n , which leads to big values of d , and minimizing ϕ_n , which leads to small values of d . The choice of penalty function is crucial for this balance to yield good results.

Several penalty functions are in use, each of them motivated by certain considerations. There is no general agreement as to which penalty function works best, partly because there are several reasonable criteria for “best”. Three examples for models of dimension d are

$$\begin{aligned} \text{AIC}(d) &= d, \\ \text{AICC}(d) &= \frac{nd}{n-d-1}, \\ \text{BIC}(d) &= \frac{1}{2}d \log n. \end{aligned}$$

The abbreviations are for *Akaike’s Information Criterion*, Akaike’s information corrected criterion, and *Bayesian Information Criterion* respectively.

It seems reasonable to choose a penalty function such that as $n \rightarrow \infty$ the value \hat{d}_n that maximizes the penalized likelihood converges to the true value (in probability or almost surely). By the following theorem penalties such that $\phi_n(d) \rightarrow \infty$ faster than $\log \log n$ achieve this aim in the case of ARMA processes. Here an ARMA(p, q) process is understood to be exactly of orders p and q , i.e. the leading coefficients of the polynomials ϕ and θ of degrees p and q are nonzero.

13.18 Theorem. Let X_t be a Gaussian causal, invertible stationary ARMA(p_0, q_0) process and let $(\hat{\theta}, \hat{p}, \hat{q})$ maximize the penalized likelihood over $\cup_{p+q \leq d_0} (\Theta_{p,q}, p, q)$, where for each (p, q) the set $\Theta_{p,q}$ is a compact subset of \mathbb{R}^{p+q+1} consisting of parameters of a causal, invertible stationary ARMA(p, q) process and $d_0 \geq p_0 + q_0$ is fixed. If $\phi_n(d)/n \rightarrow 0$ and $\liminf \phi_n(d)/\log \log n$ is sufficiently large for every $d \leq d_0$, then $\hat{p} \rightarrow p_0$ and $\hat{q} \rightarrow q_0$ almost surely.

Proof. See Azencott and Dacunha-Castelle (1984), Chapitre XIV. ■

The condition on the penalty is met by the BIC penalty, but not by Akaike's penalty function. It is observed in practice that the use of Akaike's criterion overestimates the order of the model. The AICC criterion, which puts slightly bigger penalty on big models, is an attempt to correct this.

However, choosing a model of the correct order is perhaps not the most relevant criterion for "good" estimation. A different criterion is the distance of the estimated model, specified by a pair of a dimension \hat{d} and a corresponding parameter $\hat{\theta}$, to the true law of the observations. Depending on the distance used, an "incorrect" estimate \hat{d} together with a good estimate $\hat{\theta}$ of that dimension may well yield a model that is closer than the estimated model of the correct (higher) dimension. For ARMA processes the AIC criterion performs well in this respect.

The AIC criterion is based on the Kullback-Leibler distance.

13.19 EXERCISE. Repeatedly simulate a MA(1) process with $\theta = .8$ for $n = 50$ or $n = 100$.

- (i) Compare the quality of the moment estimator and the maximum likelihood estimator.
- (ii) Are the sampling distributions of the estimators approximately normal?

13.20 EXERCISE. Find best fitting AR and ARMA models for the Wölfer sunspot numbers (object `sunspots` in `Splus`).
